Acc.
15.12.87

ISSN 0007-1250

Published by
The Royal College of Psychiatrists

NOTICE TO CONTRIBUTORS

1. *The British Journal of Psychiatry* is published monthly under the auspices of the Royal College of Psychiatrists. The *Journal* publishes original work in all fields of psychiatry. Communications on general editorial matters, including manuscripts for publication, printed matter, and books for review, should be sent to *The Editor, The British Journal of Psychiatry, 17 Belgrave Square, London SW1X 8PG.*

2. Contributions are accepted for publication on the condition that their substance has not been published or submitted for publication elsewhere. The *Journal* does not hold itself responsible for statements made by contributors. Unless so stated, material in the *Journal* does not necessarily reflect the views of the Editor or the Royal College of Psychiatrists.

3. Published articles become the property of the *Journal* and can be published elsewhere, in full or in part, only with the Editor's written permission.

4. Manuscripts accepted for publication are subject to copy-editing, and to editorial changes required for conformity with *Journal* style.

5. We regret that papers unsuitable for publication will not be returned.

6. **General advice to authors** In the assessment of manuscripts submitted to the *Journal*, great importance is attached to clarity and brevity of expression. Authors should read *General Notes on the Preparation of Scientific Papers* (3rd ed. 1974, £0.45, from The Royal Society) and/or Judith Butcher's *Typescripts, Proofs and Indexes* (1980, Cambridge University Press, £2.95). Spelling should follow the *Concise Oxford Dictionary*.

The standard of statistical work in papers submitted for publication has proved to be very variable. Authors using any statistical methods at all are strongly advised to study the paper 'Statistical guidelines for contributors to medical journals' (D. G. Altman *et al*, *British Medical Journal*, 7 May 1983, **286**, 1489–1493) at the earliest possible stage in preparing their work for publication.

7. **Manuscripts** Two high-quality copies should be submitted and the author should retain a copy. Articles must be typed on one side of the paper only, **double spaced with wide margins**, and all the pages must be numbered sequentially, starting with the title page.

a. The **title** should be brief and to the point. If necessary, a sub-title may be used to amplify the main title. The names of the authors should appear on the title-page, and **their names, degrees, affiliations and full addresses at the end of the paper.**

b. A **summary** should be given at the *beginning* of the article. It should be brief and factual and not normally more than 150 words.

c. **References** should be listed **alphabetically** at the end of the paper, **the titles of journals being given in full.** Authors should follow *Journal* style for the reference list and study the examples given below. Titles of books and journals are printed in italic and should therefore be underlined on the typescript. Reference lists not in *Journal* style will be returned to the author for correction.

Authors should check that the text references and the reference list are in complete agreement as regards dates and spelling of names. The text reference should be in the form '(Smith, 1971)' or 'Smith (1971) showed that . . . '

DURKHEIM, E. (1897) Le Suicide. Paris. Translated (1952) as Suicide: A Study in Sociology, by J. A. Spaulding & C. Simpson. London: Routledge & Kegan Paul.

KENDELL, R. E. (1974) The stability of psychiatric diagnoses. British Journal of Psychiatry, **124**, 352–358.

RUTTER, M., TIZARD, J. & WHITMORE, K. (1970) Education, Health and Behaviour. London: Longman.

SCOTT, P. D. (1974) Definition, classification, prognosis and treatment. In Pathology and Treatment of Sexual Deviation (ed. I. Rosen) Oxford: Oxford University Press.

'Personal Communications' need written authorisation.

d. **Symbols and abbreviations** Follow *Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors* (3rd ed. 1977), £2.00, available from the Publications Office of the Royal Society of Medicine. Terms or abbreviations which might not be understood by the average reader should be explained at first occurrence.

e. **Tables and Figures** Each table should be on a separate sheet, with an adequate heading; table and heading should be self-explanatory without reference to the text. The desired position of the table relative to the text should be indicated in the left margin.

Figures should be individual glossy photographs, or other camera-ready prints, *not* photocopies, clearly numbered and captioned below. Avoid cluttering figures with explanatory text which is better incorporated succinctly in the caption. A figure intended to occupy a single column should be drawn (or photographed) 80–110 mm wide to allow for a 2/3 reduction; a figure requiring the whole width of the page should be 180–210 mm wide. Lettering (film-set or stencil) should be 12pt sans (initial capital for the first word only) to give 8pt on the printed page. Labels on graphs should read parallel to the axes. Units must be clearly indicated and should be in brackets (*note*—'litre' should be spelled out in full unless modified to ml, dl, etc.).

f. **Photographs** Prints must be taken directly from the original b/w negative (not, for example, from a colour slide or a printed page) and should be glossy and sharply focussed. Labels, arrows, etc. should be shown on a duplicate print or overlay. Do not write anything on photographic prints, and do not use staples or paper-clips on them. These procedures apart, all the comments on figures and tables apply equally to photographs.

8. **Proofs** A proof will be sent to the senior author of an article. Reprints, which are prepared at the same time as the *Journal*, should be ordered when the proof is returned to the Editor.

9. **Letters to the Editor** Letters should not exceed two double-spaced typed pages. They will be edited for clarity and conformity with *Journal* style and may be shortened. There should be no more than five references; tables and figure cannot be used.

Models for Mental Disorder
Conceptual Models in Psychiatry
by PETER J. TYRER and DEREK STEINBERG

The theory and practice of psychiatry remains fragmented despite many attempts to induce consistency into the subject. The main reasons for this lack of consistency are to be found in the different schools of psychiatry, predominantly the organic (sometimes described as medical), psychodynamic (psychoanalytical), behavioural and social psychiatric schools.

Epilepsy in Young People
Edited by EUAN ROSS and DAVID CHADWICK

Epilepsy is a serious and complicated disorder in any patient but when it occurs in schoolchildren and young adults special problems are encountered. This book tackles the issues under three main headings. Section One deals with the social implications of epilepsy in young people, for example in education and employment, driving and in personal relationships. In Section Two the latest therapies are described: choosing appropriate therapy, when and how to treat with drugs, non-drug therapy, and the problems of drug withdrawal. Finally, the authors on chapters in Section Three present the latest research in epilepsy, concentrating on non-convulsive status epilepticus, ambulatory EEG monitoring, photosensitivity and new investigatory techniques.

Ecological Studies of Family Life
by ARLENE VETERE and ANTHONY GALE, University of Southampton, with SUE LEWIS, CLAIRE JOLLY and SHIRLEY REYNOLDS

Research on the family and family behaviour has largely been neglected by psychologists in recent years. This volume examines the reasons for that neglect and describes participant observation of family life. It is based on a fresh approach to family research, since the researchers lived in the family home for extended periods to observe family interaction. They evaluate existing theories of family behaviour and offer a critique of general system theory.

WESTERN REGIONAL HEALTH CENTRE

PSYCHIATRIST

The opportunity:
To join our present team of 4 Psychiatrists who in conjunction with our multi-disciplinary team provide services in our Out-Patient unit, Day Hospital, Occupational Therapy wing and In-Patient unit.

The person:
We are seeking a highly motivated individual who will contribute to the development of services in our modern facility. Candidates must obtain registration for practice in Nova Scotia which requires LMCC or FLEX (applicants must have completed the Medical Council of Canada Evaluating Examination MCCEE to write LMCC). Temporary registration may be available for up to one year while completing LMCC.

The organization:
The Western Regional Health Centre, consists of a fully accredited 175 bed hospital, an Adult Residential Centre, a Nursing Home and a School of Nursing and is located in a Seaport town in South Western Nova Scotia. There are convenient facilities and transportation services to larger centres (Boston, Halifax).

Other attractions include a salary range of $60,000 to $75,000 and bonuses available up to $25,000 dependent upon qualifications, assistance for moving expenses, private practice possible and other substantial benefits including educational leave.

Please submit a Curriculum Vitae to, or for further information, contact:

THE ANALYSIS OF DEFENSE

The Ego and the Mechanisms of Defense Revisited

Joseph Sandler with Anna Freud

Psychoanalysis has developed and expanded greatly since the late Anna Freud's *The Ego and the Mechanisms of Defense* was first published in 1936. This volume updates the original by means of discussions, primarily between Joseph Sandler and Anna Freud, which throw light on many obscure portions of the original work, indicate changes in Anna Freud's thinking, and amplify many of her initial statements. Joseph Sandler—whose formulations are at times at variance with Anna Freud—and the other participants provide an exciting springboard for the discourse.

CONTENTS: Preface. THEORY OF THE MECHANISMS OF DEFENSE. The Ego as the Seat of Observation. The Application of Analytic Technique to the Study of the Psychic Institutions. The Ego's Defensive Operations Considered as an Object of Analysis. The Mechanisms of Defense. Orientation of the Processes of Defense According to the Source of Anxiety and Danger. EXAMPLES OF THE AVOIDANCE OF OBJECTIVE UNPLEASURE AND OBJECTIVE DANGER: PRELIMINARY STAGES OF DEFENSE. Denial in Fantasy. Denial in Word and Act. Restriction of the Ego. EXAMPLES OF TWO TYPES OF DEFENSE. Identification with the Aggressor. A Form of Altruism. DEFENSE MOTIVATED BY FEAR OF THE STRENGTH OF THE INSTINCTS ILLUSTRATED BY THE PHENOMENA OF PUBERTY. The Ego and the Id at Puberty. Instinctual Anxiety During Puberty. Conclusion. Index.

Springer for Psychiatry

Emil Kraepelin

Memoirs

Editors: H. Hippius, G. Peters, D. Ploog, München

With contributions by P. Hoff, A. Kreuter

Translated by C. Wooding-Deane

1987. 23 figures. Approx. 250 pages. Hard cover DM 46,–
ISBN 3-540-17580-6

Kraepelin's work on psychiatric nosography and systematics still continues to be of topical interest nowadays. Psychiatric diagnosis throughout the world is based on his studies, which was also of outstanding significance for the development of psychiatric research. Current areas of investigation, such as psychopharmacology, psychiatric epidemiology, transcultural psychiatry and psychiatric genetics were all either founded, inspired or decisively supported by Emil Kraepelin.

Search for the Causes of Schizophrenia

Editors: H. Häfner, W.-F. Gattaz, Mannheim; **W. Janzarik,** Heidelberg

1987. 35 figures. Approx. 420 pages. Hard cover DM 128,–
ISBN 3-540-17376-5

This book is a comprehensive report of the present state of knowledge in the main areas of schizophrenia research. It presents a critical evaluation of this knowledge with the aim of formulating new working hypotheses and research strategies in the search for the causes of the disease.

H. Göppinger, Tübingen

Life Style and Criminality

Basic Research and Its Application: Criminality Diagnosis and Prognosis

With Collaboration of M. Bock, J.-M. Jehle, W. Maschke

1987. Soft cover. ISBN 3-540-16688-2. In preparation

This monograph compares the biographies of young adult inmates with a random sampling of young men from the general population and considers the results in the light of other studies of similar nature, primarily from the Anglo-American literature. For the practitioner, such an approach allows a differential assessment of the individual offender in the context of his social relationships with conclusions regarding prognosis and therapeutic effects.

The Role of the Juvenile Court

Editor: F. X. Hartmann, Cambridge/Massachusetts

1987. 8 figures, 25 tables. Approx. 392 pages. Hard cover
DM 110,–. ISBN 3-540-96461-4

From the preface: "The editors of this book take certain positions regarding the future of the juvenile justice system and what the system should look like ten years from now."

Volume 3
Families, Schools, and Delinquency-Prevention

Editors: G. C. Loury, J. Q. Wilson, Cambridge/Massachusetts

1987. 1 figure, 13 tables. Approx. 320 pages. Hard cover DM 95,–
ISBN 3-540-96434-7

This volume asks if there are ways to intervene early in a child's life that might reduce, at a reasonable cost, the probability of his becoming a serious delinquent. The results of some small-scale social experiments have been published suggesting that certain kinds of preschool education and parent training might have desirable and lasting effects.

Psychological Treatment of Mental Illness

Research and Design

Editors: R. J. Daly, Wilton; **E. A. Sand,** Brussels

1987. 28 figures, 22 tables. Approx. 170 pages.
Hard cover DM 98,–. ISBN 3-540-17596-2

M. A. Myers, S. M. Talarico, Athens, Georgia

The Social Contexts of Criminal Sentencing

1987. Approx. 12 figures. Approx. 245 pages. (Research in Criminology). Hard cover DM 98,–. ISBN 3-540-96483-5

The authors expand the scope of previous inquiry by examining not only selected characteristics of the court and sentencing judge, but also aspects of the surrounding community, such as its degree of urbanization and amount of economic inequality.

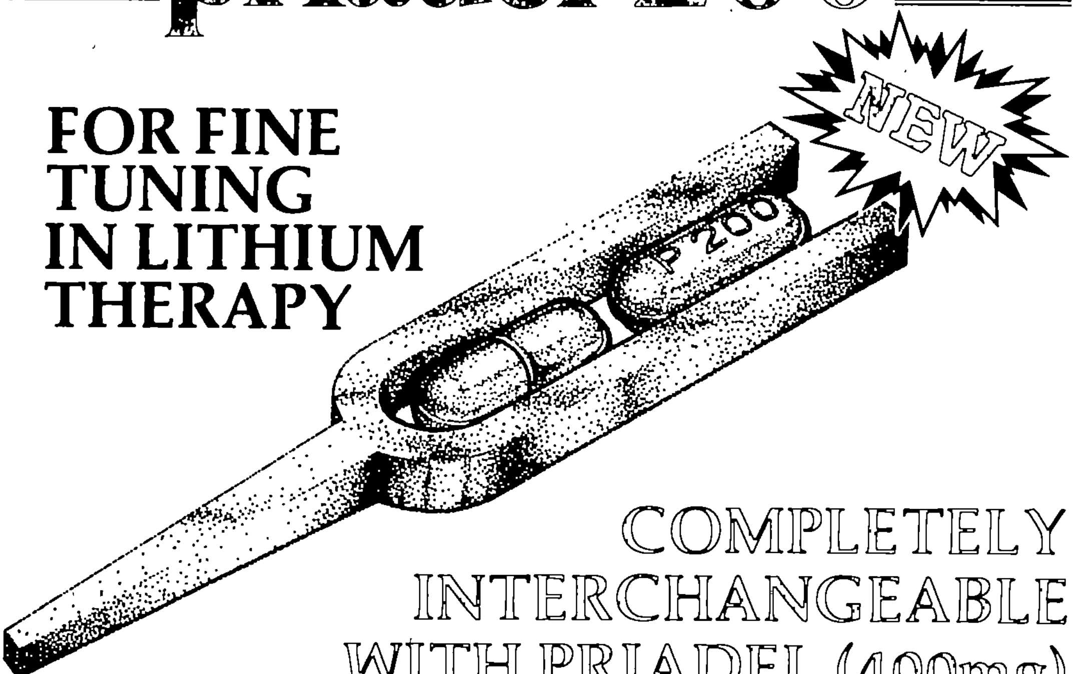
priadel® 200

FOR FINE TUNING IN LITHIUM THERAPY



COMPLETELY INTERCHANGEABLE WITH PRIADEL (400mg) WITHOUT RE-STABILISATION

priadel® — the world's first controlled release lithium now offers maximum flexibility of dosage

PRESCRIBING INFORMATION

Presentation
Each Priadel 200 Tablet contains 200mg lithium carbonate Ph.Eur. in a controlled release formulation. Also Priadel Tablets each containing 400mg lithium carbonate in the same controlled release formulation.

Indications
Treatment and prophylaxis of all elements of affective illness. For the control of aggressive or self-mutilating behaviour.

Dosage
In patients of average weight (70kg) 400—1200mg daily as a single dose, usually on retiring. Check serum lithium level at least 12 hours after the last dose on day 4 or 5. The twelve-hour serum level should be in the range 0.7—1.0 mmol/l. Adjust dose where necessary and check serum lithium level weekly until stabilisation has been achieved.

Contra-indications, warnings etc.
Renal and cardiovascular insufficiency. Addison's disease and untreated hypothyroidism. Recommendation to discontinue Priadel before planned pregnancy and for the first trimester. Exercise care in circumstances where electrolyte balance may be disturbed due to concurrent infections or other medication, for example diuretics, appetite suppressants and steroids. See Data Sheet for reported possible drug interactions.

Side effects and precautions
Initiation of lithium therapy may give rise to transient side effects which usually disappear following stabilisation. These include fine hand tremor, weight gain, polydipsia, polyuria and anorexia. Nausea and diarrhoea which are related to the site and rate of absorption are minimised by the controlled release formulation of Priadel. Long-term treatment with lithium may be associated with disturbances of thyroid or renal function which should be monitored.

Toxic effects which may be indicative of impending lithium intoxication include: increasing anorexia, diarrhoea, vomiting, muscle weakness, lack of co-ordination, drowsiness or lethargy progressing to giddiness with ataxia, tinnitus, blurred vision, dysarthria, seizures and coma.

The Retreat, York

for Psychiatric Illnesses

Founded in 1792 by the Quaker, William Tuke, who established the tradition of concern for patients as individuals The Retreat is a 200-bedded private registered nursing home surrounded by extensive grounds on the outskirts of the historic City of York. It is easily reached by rail and motorways.

Care and treatment is offered for all types of psychiatric illness on the short or long term in a sympathetic and friendly atmosphere. Patients suffering from neuroses, psychoses, alcoholism and dementia are treated by the full-time consultant psychiatrists in surroundings suitable for their individual needs. Outpatient facilities are available by appointment with the consultant medical staff.

The Nursing Home is a registered charity and is able to offer inclusive care in shared accommodation from £32.00 per day or in single rooms at slightly increased charge. The Nursing Home is recognised by the main private patient schemes.

For further details apply to The Medical Director, The Retreat, York YO1 5BN (Telephone 0904 412551).

When depression is the source of anxiety...

PROTHIADEN

Dothiepin Hydrochloride B.P.

restores peace of mind

Differential diagnosis of depression and anxiety is rarely clear cut. Your typically middle-aged female patients will usually present with symptoms of both. The potential risks of an inappropriate choice of treatment for these patients can often be a cause for concern.

Prothiaden, with its well-proven ability to relieve both depression and anxiety, can alleviate this concern. A prescription for Prothiaden ensures that neither aspect of your patients' problem is left untreated.

So, in this complex diagnosis, Prothiaden has an additional benefit – relieving your anxiety as well as that of your patients.

PRESCRIBING INFORMATION

Presentation: Prothiaden is Dothiepin Hydrochloride B.P. an antidepressant of the tricyclic group. It is available as 25mg capsules and 75mg tablets. **Uses:** Prothiaden is indicated in the treatment of depression and associated anxiety. **Dosage:** Prothiaden should be given in a dosage of 75 to 150mg daily, based on response and severity. This may be taken as a single evening dose. In certain circumstances, i.e. in hospital use, Prothiaden has been given in dosages up to 225mg daily. Elderly – half the normal dose may be sufficient. **Precautions and Contra-indications:** Prothiaden has anticholinergic properties, therefore, it may precipitate urinary retention in susceptible individuals and its use should be avoided in patients with existing or potential urinary retention. Prothiaden should not be used in patients with closed-angle glaucoma. Caution is advised when treating epileptic patients and those with cardiovascular disorders. Prothiaden should not be used with MAO inhibitors nor within 14 days of ceasing such treatment. It may modify the action of some CNS depressants, catecholamines and hypotensive agents. **Side Effects:** These are usually mild and normally controlled by reducing the dosage. The following have been reported: dryness of mouth, constipation, disturbed accommodation, orthostatic hypotension, palpitations, somnolence, tremor, headache. **Basic N.H.S. Price:** 28 x 75mg £4.00 as at 1st Nov. 1986. **Product Licence Numbers:** PL0014/5941 PL0014/0209. The Boots Company PLC, Nottingham. England. Further information available on request.

British Journal of Psychiatry (1987), **151**, 1–8

Assessing the Functional Value of Relatives' Knowledge about Schizophrenia: A Preliminary Report

C. BARROWCLOUGH, N. TARRIER, S. WATTS, C. VAUGHN, J. S. BAMRAH and H. L. FREEMAN

An instrument for assessing and evaluating what relatives know about schizophrenia was evaluated as both a pre- and a post-test for an educational programme. The Knowledge About Schizophrenia Interview (KASI) places emphasis on the functional value of the reported knowledge rather than on the recall of information; it is quick, easy to administer, can be rated reliably, and has face-validity for the relative. The educational programme increased scores from pre-test to a post-test one week after the programme. Relatives with high criticism ratings on the Camberwell Family Interview had lower scores at both tests. Relatives of less chronic patients showed lower scores at pre-test and acquired significantly more information from the programme, while relatives of more chronic patients were less influenced by the information sessions.

Several recent studies (e.g. Berkowitz *et al*, 1984; McGill *et al*, 1983) have reported on giving information about schizophrenia to relatives, generally as part of larger psychosocial interventions that attempt to reduce relapse rates of patients suffering from schizophrenia who return to live with their families (Goldstein, 1981; Barrowclough & Tarrier, 1984). It can be argued that both relatives and people suffering from schizophrenia should have, as their right, access to information about the condition; but in addition, informing carers about schizophrenia may in fact contribute to an improvement in the condition.

The index of Expressed Emotion (EE) has been important in studying schizophrenics' families and relapse (Leff & Vaughn, 1985). Relatives are measured as being "high-EE" or "low-EE" on the basis of the number of critical comments and the extent of emotional over-involvement or hostility shown to the patient during a recorded, semi-structured Camberwell Family Interview (CFI) (Vaughn & Leff, 1976*b*). A number of studies have found an association between relapse of schizophrenia within nine months of discharge and the EE of the key relative residing with the patient (Brown *et al*, 1972; Vaughn & Leff, 1976*a*; Vaughn *et al*, 1984). Patients returning to live with high-EE relatives had significantly higher relapse rates than those going to low-EE relatives, independent of all other factors assessed.

It has been suggested (Vaughn & Leff, 1981) that high-EE relatives tend to feel that patients could control their symptomatic behaviour, and take a relatively unsympathetic view of the illness, whereas low-EE relatives believe that the patients suffer from a legitimate illness and cannot control certain behaviour. Since Brown *et al* (1972) suggested that a major contribution to high-EE was lack of knowledge by the relative about schizophrenia, it has been hypothesised that educating relatives, by giving them information about schizophrenia, might lead to reduced criticism and hostility and a lowering of EE (Berkowitz *et al*, 1984; McGill *et al*, 1983). However, the study of Berkowitz *et al*, failed to support the hypothesis that high-EE relatives know less about schizophrenia than low-EE relatives.

Tarrier & Barrowclough (1986) have discussed some of the issues involved in giving relatives information about schizophrenia and have questioned the utility of measuring acquired information *per se*. This article describes the development of an instrument designed to assess the *functional value* of the relative's knowledge about schizophrenia, which was part of a larger study investigating the effects of psychological intervention in families, including an educational component.

Method

Patients

All patients admitted to the acute wards of a large psychiatric hospital and the psychiatric ward of a general hospital within one health district were screened. Patients were included within the study if they met the following criteria:

1. Having a diagnosis of schizophrenia elicited by use of the Present State Examination (Wing *et al*, 1974) by a trained interviewer (JB, CB, NT, SW, HF).
2. Age on admission 16–65 years.

3. Residing with someone (e.g. parent, spouse, sibling, friend, partner) for at least three months prior to admission, and returning to this residence on discharge.
4. Having no evidence of an organic condition to explain the psychopathology.

Relatives

On the patient being recruited into the study, the relatives were contacted and the CFI was carried out and audiotaped by a trained interviewer (CB, NT, SW). Relatives were allocated to the education programme in accordance with the stratified random design of the larger intervention study; 24 relatives (related to 17 patients) were assessed and given the education programme. Relevant characteristics of these relatives and patients can be seen in Table I. All relatives allocated to the education programme received both sessions described below.

The education programme

Relatives were given a hospital appointment to attend an education session during the first week after discharge (Session 1) and another one week later (Session 2). Two relatives preferred the sessions to be given at home; this was arranged.

Session 1

The relative was interviewed and audiotaped, using the *Knowledge about Schizophrenia Interview* (KASI): if more than one relative of the patient attended, each relative was interviewed separately. All relatives aged 16 years or above who lived with the patient were encouraged to attend.

After the pre-test, relatives were given an information booklet (Barrowclough *et al*, 1986); the content of the booklet was worked through with one of three interviewers (CB, NT, SW). Particular attention was paid to:

(i) areas of information highlighted as being 'incorrect' or not known during the pre-test
(ii) describing the particular patient's psychotic symptoms, elicited by the PSE.

If more than one relative attended, the education part of the session was conducted with all the relatives together. The patient was interviewed simultaneously but separately, and given the same information as the relative(s). Questions from relatives were encouraged and prompted, taking into account information from the pre-test interview and including such questions as: "You said earlier that you thought X might be better off without medication. What do you think about that now?" or "You said earlier that you didn't think stress had anything to do with Y's illness; what do you feel about this now?".

In the latter part of the session, patient and relative(s) were seen together, and further questions encouraged.

At the end of the session, the relatives were given an appointment for Session 2, one week later; they were asked to take the booklet away with them and to read it thoroughly. (The booklet is written in simple terms and has been assessed by the Flesch reading scale (Flesch, 1948) as being understandable to 75% of the population.) Relatives were told that the main function of the subsequent session was to answer any further questions that they might have.

Thus Session 1 consisted of three stages:

(i) KASI pre-test (relatives tested individually)
(ii) information giving and question/feedback (relatives together, patient separately)
(iii) further questions/feedback (relatives and patient together).

TABLE I

Characteristics of 17 schizophrenic patients and 24 relatives with whom they lived

Patients (n = 17)	
Male/Female	7M/10F
Living with:	
Parents	11
Spouse/partner	5
Child	1
Age (years):	
Mean	37
Median	39
Range	16–60
Number of previous hospital admissions:	
Mean	3.2
Median	3
Range	0–13
First admission	*n* = 2
Years since onset:	
Mean	6.6
Median	4
Range	0–24
Relatives (n = 24)	
Relationship to patient:	
Mother	9
Father	6
Spouse/partner	6
Daughter	2
Sibling	1
EE status	High 20/ Low 4
Reason for high-EE rating:	
Emotional over-involvement (EOI)	*n* = 5
> 5 critical comments (CC)	*n* = 3
EOI + CC	*n* = 3
EOI + CC + hostility	*n* = 3
CC + hostility	*n* = 6
Current/previous employment	
Unskilled	14
Skilled manual	2
White-collar	7
Professional	1

Session 2

There were two stages: (i) *Questions/feedback*, during which the relatives and the patient were seen together, and asked if they had any further questions or if there was any further issue they wished to discuss; and (ii) *KASI (post-test)* during which the relative(s) were interviewed individually and audiotaped.

This procedure for the educational programme—two sessions with a one-week interval—was adopted because:

- (i) Relatives occasionally became worried, or misunderstood the information they were given. An early second appointment allowed an opportunity to discuss any such problems.
- (ii) KASI assessment one week after the education session was thought to be more likely to assess longer-term information retention than a test given immediately after the education session.
- (iii) The one-week period allowed relatives and patients time to discuss the information and to read the booklet.
- (iv) The possibility of the outcome evaluation (KASI post-test) being affected by factors other than the education programme was minimised.

The KASI interview

The KASI and its rating criteria were designed in accordance with the following objectives:

1. Items should assess not just the presence or absence of information about schizophrenia, but the effects of that information on the relative's behaviour.
2. The items should be phrased simply, and the absence of academic or technical knowledge should not be penalised in the scoring.
3. Administration and scoring of the interview should be relatively quick and required the minimum of training.

As with comparable instruments (e.g. Berkowitz *et al*, 1984; McGill *et al*, 1983) the following aspects of the schizophrenic condition were covered:

1. Diagnosis
2. Symptomatology
3. Aetiology
4. Medication
5. Course and prognosis
6. Management

Each topic was covered in a different section which could be scored independently. Most questions were structured so as to require a "Yes/No/Don't know" choice, but the section, on management contained open questions. In selecting items, the following questions were borne in mind:

1. What information might have a beneficial influence on the relative's behaviour in relation to the patient?
2. Conversely, what perceptions, attitudes, and reported behaviour might have undesirable effects on the relative's behaviour in relation to the patient?

The interview was developed to permit the allocation of the relative's responses for each section to one of four categories:

1. *Negative value*: Relative reports information which may lead to potentially detrimental actions in regard to the patient's management.
2. *Neutral value*: Relative knows very little or nothing, but reports no information which would probably result in detrimental management.
3. *Positive value*: Relative reports information which may lead to potentially valuable actions in regard to the patient's management.
4. *Positive value and additional correct information*: Over and above the information for category 3, the relative demonstrates wider knowledge about the assessed aspect of the condition.

Some examples of how these criteria were applied are given in the Appendix at the end of this paper. Further details of the interview and the scoring criteria may be obtained from the authors (Barrowclough *et al*, 1985).

For each of the six sections of the KASI, the relative's responses were allocated a score on the 1–4 scale described above. Both interviews for all 24 relatives were scored by CB. Ten interviews were then selected randomly and scored independently by NT for reliability calculations.

Results

Reliability

The degree of inter-rater agreement between the two independent raters (CB and NT) for each of the six sections of the KASI is shown in Table II. These data are based on the two independent raters scoring ten randomly selected audiotaped interviews with ten different relatives (60 sections of interview). It was concluded that the scores obtained were of acceptable reliability and that this finding might be generalised from the random sample to the total population of audiotapes scored by CB.

1. KASI scores before/after education

A Wilcoxon matched-pairs test was performed on the data for all 24 subjects, comparing pre-test and post-test scores

TABLE II

Inter-rater agreement for each of the six sections in the audiotaped KASI

Section of interview	*Percentage agreement*	*Weighted κ coefficient*
1. Diagnosis	80%	0.70 ($P<.01$)
2. Symptomatology	80%	0.66 ($P<.01$)
3. Aetiology	100%	1.00 ($P<.01$)
4. Medication	80%	0.64 ($P<.01$)
5. Course and prognosis	90%	0.78 ($P<.05$)
6. Management	80%	0.66 ($P<.05$)

TABLE III

KASI scores before and after the educational programme. Relatives' responses were rated as 1 (negative), 2 (neutral), 3 (positive) or 4 (positive + well-informed)

Section of KASI	*Pre-Test Scores ($n=24$)*				*Post-Test Scores ($n=24$)*				*Wilcoxon pairs test (z scores)*	*McNemar test (χ^2)*
	Median	*Range*	*Score 1 or 2*	*Score 3 or 4*	*Median*	*Range*	*Score 1 or 2*	*Score 3 or 4*		
1. Diagnosis	2	1–4	$n=16$	$n=8$	3	1–4	$n=3$	$n=21$	3.3 ($P<0.0005$)	15.08 ($P<0.001$)
2. Symptomatology	2	1–3	$n=13$	$n=11$	3	1–4	$n=7$	$n=17$	2.4 ($P<0.008$)	7.2 ($P<0.01$)
3. Aetiology	2	1–2	$n=24$	$n=0$	2	2–4	$n=14$	$n=10$	2.93 ($P<0.002$)	12.1 ($P<0.001$)
4. Medication	3	1–4	$n=6$	$n=18$	3	1–4	$n=3$	$n=21$	1.52 ($P<0.06$)	3.2 ($P<0.08$)
5. Course & prognosis	2	1–4	$n=20$	$n=4$	3	1–4	$n=11$	$n=13$	2.93 ($P<0.002$)	11.11 ($P<0.001$)

Total KASI score	13.5	7–18	$n=90$	$n=54$	17	8–21	$n=43$	$n=101$	3.85 ($P<0.0001$)	44.18 ($P<0.001$)

and using a one-tailed test of probability (we made the *a priori* assumption that there would be either an increase or no change in knowledge). The results (*z* scores) are shown in Table III. Scores for sections 1,2,3,5, and 6 increased significantly between tests, as did the total score (the sum of all the section scores). Scores on section 4 (medication) showed an increase which approached statistical significance.

A McNemar test was also performed to compare scores on pre- and post-test, for each section and for total scores; change from a score of 1 or 2 to 3 or 4 was tested. The results are presented in Table III, which shows a significant change from category 1 or 2 to 3 or 4 for total scores and for all sections except medication. Whereas 31 sections received a rating of 1 at pre-test, only 11 were rated 1 at post-test; 15 relatives had at least one section given a score of 1 at pre-test, compared to only seven at post-test.

2. Relatives' characteristics and KASI scores

(a) Critical/non-critical relatives

For the purposes of this analysis, ratings of hostility and emotional over-involvement were ignored. Relatives were divided into those who expressed six or more critical comments during the CFI, and so were rated 'high-EE' ($n=15$); and those who expressed five or less critical comments ($n=9$). Three Mann-Whitney U tests were carried out to compare total scores between the two groups at pre-test and at post-test, and change scores:

Comparison	*z*	*P (two-tailed)*
Pre-test total score	1.99	0.05
Post-test total score	2.28	0.02
Change scores	0.64	NS

At pre-test, relatives with fewer critical comments had a significantly higher total score (median 14, range 10–18) than those with more critical comments (median 12, range 7–17). Similarly at post-test, scores were significantly higher for the less critical group (median 19, range 12–21) than for the more critical group (median 17, range 8–18).

(b) Emotional over-involvement (EOI)

Relatives were divided into those who scored 3 or more on EOI ($n=11$) and those who scored 2 or less ($n=13$). Hostility and critical comments were ignored for this analysis. Mann-Whitney U tests were carried out to compare the two groups on total scores (pre- and post-tests) and on change scores. No significant differences were found between the two groups.

(c) Hostile/non-hostile relatives

Relatives were divided into two groups, according to their hostility rating (hostile $n=9$, non-hostile $n=15$). EOI and critical comments were ignored for this analysis. Mann-Whitney U tests were carried out on the total scores for pre-test and post-test, and on change scores. No significant differences were found between the two groups.

(d) Relationship with patient

Relatives were divided into two groups according to whether they were the parents of the patient ($n=15$) or were related in another way (e.g. spouse, child, sibling: see Table I) ($n=9$). Mann-Whitney U tests were carried out on total scores at pre-test and post-test and on change scores. No significant differences were found.

3. Patients' characteristics and KASI scores

(a) Duration of illness

Relatives were divided into two groups, based on a median split of the number of years since the onset of the patient's illness (calculated from the first hospital admission). For the 'less chronic' patient–relative group, the median number of years since onset was 2.5, with a range of 0–3 years. For the 'more chronic group', the median was 7, with a range of 4–24 years. A Mann-Whitney U test was carried out on total scores at pre-test and post-test and on change scores:

Comparison	*z*	*P (two-tailed)*
Pre-test total scores	1.76	0.08
Post-test total scores	1.91	0.06
Change scores	2.71	0.007

Relatives of 'less chronic' patients had significantly higher change scores (median 6, range 0–10) than relatives of 'more chronic' patients (median 3, range -1–$+10$)

At pre-test, relatives of 'less chronic' patients had lower scores (median 13, range 7–18) than those of 'more chronic' patients (median 14, range 12–17); but at post-test, the position was reversed (less chronic: median 17.5, range 8–21; more chronic: median 15.5, range 12–18). These pre-test and post-tests comparisons just failed to reach significance.

(b) Number of hospital admissions

Relatives were divided into two groups, based on a median split of the number of times the patient had been admitted to hospital. A Mann-Whitney U test was carried out on total scores at pre-test and post-test and on change scores: no significant differences were found between the two groups.

(c) Remission of symptoms

Relatives were divided into two groups, depending on whether the patient experienced positive schizophrenic symptoms continuously, or had had remission of symptoms in between episodes of illness. Mann-Whitney U tests were carried out on the total scores for pre-test and post-test and change scores, and showed no significant differences between the groups.

4. Summary of results

(a) There was a significant increase in individual scores between tests. Total scores showed a significant increase, as did scores on all the different sections of the KASI except section 4 (medication), where the increase in scores closely approached significance. There was a significant change from responses of negative or neutral value to the patient to those of positive value, for all sections except medication.

(b) Relatives who were rated 'low on criticism' had significantly higher test scores at both pre-test and post-test. Relatives rated 'low' on hostility or emotional over-involvement did not show significant differences in test scores from those rated 'high'.

(c) Relatives of patients with more recent onset of illness showed lower scores at pre-test and higher scores at post-test: these differences closely approached significance. The change scores of these relatives were significantly higher.

(d) No significant differences in scores were found when relatives were grouped according to the patient's number of hospital admissions, the pattern of remissions, or the relative's familial relationship to the patient.

Discussion

This paper has described a method of assessing what relatives know about schizophrenia, and how this knowledge might be improved or changed through a relatively brief educational intervention. It is important, however, to emphasise the nature of the assessment: our concern was to categorise relatives' responses to questions about schizophrenia in terms of what significance those responses might have in either assisting or hindering the patient's recovery. In other words, our interest was in the functional value that the information potentially held, so that the relatives' responses were allocated either a negative, neutral, or positive functional value.

The results from this initial trial appear to be encouraging: relatives' knowledge (as assessed by the KASI) improved significantly after the information session. Moreover, there was a significant change in their responses, from functionally negative or neutral before the education sessions to positive afterwards. This result applied to five of the six different aspects of schizophrenia assessed and to the total score derived from all six sections of the KASI; in the case of the other section (Medication) there was improvement which closely approached statistical significance. This is evidence of the success of brief intervention in giving relatives information which might be used to assist the patients. Conversely, information which might lead to actions detrimental to the patients' recovery was significantly reduced.

A closer examination of the questions in the medication section, and relatives' responses to them, may explain why the trend towards improvement there did not reach significance. To receive a positive-value score (3), relatives were required to know some practical details about the administration of the medication; e.g. when, where and for how long it was to be given. They were also required to advocate that the patient remain on medication for as long as the doctor prescribed, when presented with other choices such as "for as long as the patient thinks she/he needs it" or "for as long as you think she/he needs it". Since most relatives had this knowledge already at pre-test, any improvement was probably limited by their initial scores. Questions about the prophylactic nature of medication (e.g. "If your relative seemed and felt completely better and decided to stop having the medication, what do you think would happen?") were contained in Section 5 of the interview ('Course and prognosis'), which showed significant improvement at post-test. Relatives could therefore agree that the doctor should decide how long the patient should receive the medication, yet make clear from their responses in Section 5 that they actually believed that the patient would be better off without it. According to the KASI, such negative responses were reduced at post-test.

The data from the relatives' responses were analysed according to the important dimensions of EE: frequency of criticism; hostility; and marked emotional over-involvement. Analyses of the data were performed taking each dimension into account independently of the other two. Only one analysis produced significant results: relatives who made six or more critical comments in the CFI tended to have significantly lower KASI scores at both pre-test and post-test. There was no significant difference between the critical and less critical groups in their change scores. These results suggest that the more critical relatives had more negative or neutral-value information about schizophrenia at pre-test, but that they benefitted as much as the less critical relatives from the education sessions. We therefore agree with Vaughn & Leff (1981) that one of the characteristic attitudes or response styles distinguishing high- from low-EE relatives is their attitude to the illness. High-EE relatives tend to doubt that the patient has a legitimate illness, and feel that he or she might do more to control the 'symptoms'. Of particular relevance to this conclusion are the responses of the relatives in our study to questions in Section 2 of the KASI, which refer to symptoms. Relatives were required to say whether the 'problems' they had reported with the patient were part of the person's illness or were associated with his or her natural self'; they were also required to state whether or not they thought the patient could control these symptoms. All four relatives in our study who were given a 'negative' score in this section (i.e. those who reported believing that most of the symptoms they observed were part of the patient's personality and/or within his or her control) were rated as critical and hostile. A larger group of relatives would be necessary to examine the statistical significance of this finding, however.

No differences were found between KASI scores when relatives were grouped on the basis of hostility or EOI ratings; but there were relatively few subjects, in the group analysis, and further investigation is necessary.

The analysis of relatives' scores in relation to the chronicity of the patients' illness produced some interesting results; chronicity was defined as the number of years since the onset of the illness, and the relatives were divided into two groups on this basis. The relatives of patients with relatively short histories had lower KASI scores at pre-test and greater change scores. These results suggest that the shorter the length of illness the less the relatives know, but the more receptive they are to acquiring information. This is consistent with an interaction model of how relatives take in information about schizophrenia (Tarrier & Barrowclough, 1986), which postulates that relatives develop an individual view of the patient's condition and bring to an education session opinions as to its causes, course, and consequences which affect their acceptance or rejection of alternative information offered to them. The longer the patient's illness, the more time the relative has had to formulate his own lay model of the illness, and the less influenced he is by professional opinion. We found no significant differences in knowledge between relatives of patients with comparatively few past hospital admissions and those with more, so one might speculate that contact with hospital psychiatric services did not influence the development of the relatives' attitudes. It is apparent that early education about the schizophrenic condition is important in influencing relatives' behaviour. Birchwood (1983) has suggested that negative family influences in schizophrenia develop as the condition becomes chronic.

If some relatives have an existing and well developed lay model of schizophrenia, it is not surprising that there may be no change in their views after a relatively brief educational intervention. Although analysis of group data indicated significant increases in information in the group as a whole, those relatives whose scores did not show improvement are important from both the research and clinical points of view. The scoring system of the KASI may be of particular use in indicating which aspects of schizophrenia are misconstrued by particular relatives; further information and advice may then be given to those most in need, and their responses re-evaluated until acceptable criteria are reached.

Berkowitz *et al* (1984) commented that relatives remembered only a fraction of what they had been told in their educational sessions. The differences in findings between their study and ours may be due to several factors, including differences in educational content and presentation, the assessment procedures used, and the time interval before retesting. Berkowitz *et al*, like McGill *et al* (1983), placed greater emphasis than us on imparting and assessing knowledge about schizophrenia *per se*, in contrast to our assessment of the potential functional value of the information in the context of the particular patient's illness. Although the education sessions reported by McGill *et al* did emphasise the symptomatology of the individual patient, this does not appear to have been reflected in the assessment procedures. Neither McGill *et al* nor Berkowitz *et al* differentiated between negative, neutral and positively valuable information. Consequently, a relative might be assessed as having given the 'correct' answer after an education session, while retaining beliefs which could lead to actions detrimental to the patient's management (see Tarrier & Barrowclough, 1986, for discussion).

The finding of Berkowitz *et al* that relatives were particularly lacking in knowledge about the aetiology of schizophrenia, and that they tended to retain their own versions of the causes of the illness, is partly supported by the results of the present study. The Aetiology section of the KASI contains an open question about causation, followed by a series of forced-choice questions regarding possible causes, and enquiries designed to investigate relatives' behaviour. At pre-test, all the relatives' responses were assessed as negative or neutral. Although there was a large and significant increase in scores at post-test, a substantial number remained in the neutral category, indicating that these relatives had learnt little about aetiology.

Conclusions

This paper has described the development and initial results of an evaluation procedure which aims to examine the information which relatives hold about schizophrenia, with a specific focus on the functional value of that information. The advantages of the instrument include ease of administration and scoring, reliability of evaluation, and sensitivity to change. The effectiveness of the educational programme has been demonstrated, although the longer-term maintenance of any improvement which the relatives showed in their knowledge has yet to be evaluated. The data will be reported when available.

Many relatives bring to the educational session well-developed and systematised knowledge of their own, and the difficulties in changing their beliefs and attitudes should not be under-estimated. Our preliminary results suggest that educational sessions are likely to have more impact on relatives of patients with a fairly short history of illness.

One of the advantages of the KASI may be the identification of relatives with beliefs and attitudes which can result in actions detrimental to the patients' well-being, and who consequently require further advice and support.

Acknowledgements

The authors would like to thank the patients and relatives for their participation; numerous staff of Salford Health Authority for their assistance; and Dr Ian Falloon for his help with the education booklet. The work was supported by the North West Regional Health Authority (Grant No. 5062).

Appendix

As described in the "Method" section of this paper, each relative's knowledge of schizophrenia and his/her corresponding attitude towards the patient was assessed as:

1 negative
2 neutral
3 positive
4 positive and well-informed

This assessment was done for each area of knowledge examined by the KASI interview. Examples to show how such assessments were made with regard to diagnosis and symptomatology are given below.

Rating relatives' knowledge of diagnosis

The section of the KASI dealing with diagnosis is concerned only with relatives' knowledge of the name of the condition and the recognition that schizophrenia is a serious mental illness which can affect all aspects of a person's life. The absence of such knowledge is not by itself considered to have direct negative functional value, and so would indicate a rating of 2 (neutral); but such ignorance combined with other erroneous information with potentially negative value would lead to the relative's allocation to category 1 (negative). Examples of negative statements would include "It's not a mental illness, it's just his personality" or "She's not mentally ill, she's a drug addict". It would be logical to suppose that in the first case the relative's denial of the patient's condition could lead to criticism of his behaviour; while the relative's attitude in the second case could lead to a failure to support compliance with prophylactic medication.

Some items in the diagnosis section were later removed because it was found that they were not after all helpful in categorising relatives' behaviour. These items included "Does schizophrenia mean the person has a split personality?" and "Are people with schizophrenia more likely to be violent?". Although strictly speaking, a negative response to these items would indicate knowledge of schizophrenia, it became clear that a positive reply had positive functional value to some relatives: the idea of a "split personality" was useful in distinguishing between the ill person who behaved in a way unlike his usual self and the healthy person. Similarly, the association of violence with schizophrenia was helpful to those people who had experienced their relatives behaving 'violently' while ill, in complete contrast to their normal selves.

Rating relatives' knowledge of symptoms

Our concern here was with relatives' attribution of the problems or symptoms they had previously reported in the CFI, as well as with their knowledge of the patient's symptoms.

To be allocated a score of 3 (i.e. to be rated 'positive'), the relative was required to attribute 60% or more of the problems or symptoms to the illness rather than to the person's natural self. The same criteria also had to apply to the relative's beliefs concerning the amount of control the patient had over the symptoms. In addition, relatives were required to identify at least *one* of the patient's diagnostic symptoms, and not to attribute this to the patient's personality or to regard it as being under his control.

The relatives' attribution of problems and their beliefs about control over symptoms were assessed through a forced-choice response; e.g. "You have mentioned that X's problems affected him by him talking to himself. Do you think this behaviour is part of X's natural self, or do you think it's part of X's condition?", and "Do you think Y could help or control talking to himself?". The relative was required to reply "Yes", "No" or "Don't know". A response of "don't know" for more than 60% of the items meant allocation to category 2 (neutral). Attribution mainly to the person's 'natural self' and/or 'own control' were allocated to category 1 (negative), on the grounds that such beliefs might have detrimental functional value; the relative might *blame* the patient for unusual or disruptive behaviour.

Abnormal Auditory Brain-stem Responses in Hallucinating Schizophrenic Patients

L. LINDSTROM, I. KLOCKHOFF, A. SVEDBERG and K. BERGSTROM

Abnormal auditory brain-stem responses (ABRs) were recorded in 10 out of 20 schizophrenic in-patients. The response abnormalities did not show any correlation to the degree of psychopathology, sub-group of schizophrenia, age, sex, or cerebral ventricular enlargement. Nor was there any correlation to previous neuroleptic treatment: a pathological ABR was recorded in 5 of the 8 patients who had never received such medication. A statistically significant relationship was found between ABR pathology and auditory hallucinations: 9 of the 11 patients who admitted having hallucinations exhibited brain-stem response abnormality, whereas ABR abnormality was recorded in only 1 of the 9 patients who denied having hallucinations. The data imply that brain-stem dysfunction is involved in the psychopathology of schizophrenia, and that interference with the auditory pathways in the brain-stem may induce auditory hallucinations in schizophrenic patients.

Schizophrenia has been found to be associated with many signs of brain dysfunction. Techniques including neuropathology, computed tomography (CT), cerebral blood flow and positron-emission tomography have contributed to the demonstration of cerebral abnormalities of various degrees in a large proportion of schizophrenic patients (for review see Seidman, 1983). Neurological so-called "soft signs" indicating brain dysfunction are also common in schizophrenia (Kennard, 1960; Pincus & Tucker, 1978): the frequency of such signs in schizophrenics has been reported to range between 36% and 75% (Hertzig & Birch, 1966; Mosher *et al*, 1971; Torrey, 1980). But although there is general agreement about the existence of brain dysfunctions in schizophrenia, opinions regarding their anatomical localisation differ. Much attention has been directed towards the limbic structures, but also towards the basal ganglia (Lindsky *et al*, 1979), corpus callosum (Rosenthal & Bigelow, 1972) and cerebellum (Health *et al*, 1982).

Several studies using different techniques have suggested the brain-stem to be the critical site for many of the symptoms observed in schizophrenic patients. The brain-stem cranial-nerve nuclei and tracts, together with the reticular formation, are responsible for sensory integration. Data indicating abnormal brain-stem function have been obtained from schizophrenic patients by testing proprioceptive mechanisms in the vestibular system (King, 1974), by continuous performance tests (Heaton *et al*, 1978), by eye tracking tasks (Holzman *et al*, 1976) and as evoked potentials on EEG (Shagass, 1975). Postmortem studies have reported brain-stem lesions of an encephalitic nature in schizophrenics (Fisman, 1975).

We present here a study which aimed to assess brain-stem function, using auditory brain-stem responses, in first-admitted as well as chronic residual schizophrenic in-patients. The data were correlated to age, sex, symptomatology, brain ventricular enlargement and medication.

Method

Patients

Twenty schizophrenic in-patients, 12 male and 8 female, participated in the study on an informed-consent basis. The median age was 27 years (range 19–44) and the median duration of illness was 3½ years (range 1 month–20 years). Eight of the patients had never been admitted to hospital before and had never received neuroleptic treatment. Diagnosis of schizophrenia was ascertained using the Research Diagnostic Criteria (RDC: Spitzer *et al*, 1977), according to which 7 cases were of the disorganised sub-type, 6 of the paranoid sub-type and 7 of the undifferentiated sub-type of schizophrenia.

Symptoms were scored using 33 items from the Comprehensive Psychopathological Rating Scale (CPRS: Åsberg *et al*, 1978). Special attention was focused on the presence or absence of auditory hallucinations. If an individual had experienced voices for at least one hour during the week preceding the brain-stem recording, auditory hallucinations were considered to be part of the symptomatology.

Nine patients had been on neuroleptic treatment for at least one month (range 1 month–16 years) when the brain-stem response was recorded. Data on the patients are presented in Table I.

TABLE I

Clinical characteristics, ventricular/brain ratios and auditory brain-stem responses of 20 schizophrenic patients

Patient number	*Sex*	*Age*	*Current neuroleptic treatment*[1]	*Total CPRS score*[2]	*Auditory hallucinations*	*Ventricular/brain ratio (VBR)*	*Auditory brain-stem responses (ABR)*

1. Receiving neuroleptics for at least one month prior to ABR recordings.
2. Comprehensive Psychopathological Rating Scale: Åsberg *et al* (1978).

ABR recording technique

The recording arrangements used in this study are based on a widely accepted technique and the normative data used in our Department of Audiology are in close agreement with those reported by Rosenhamer *et al* (1978).

Before the recording session, pure tone audiometry was performed to detect any hearing loss that might influence the recording and analysis of the ABR.

During the recording session the subjects rested comfortably on a couch in a sound-proof and electrostatically shielded room. No sedatives were given. For auditory stimulation and recording brain-stem response a Nicolet Pathfinder II-system was used. The acoustic stimuli consisted of condensation clicks which were presented unilaterally via TDH-39 headphones at a rate of 21.3 clicks per second, a mode of stimulation that was found to produce a minimum of aliasing errors. No contralateral masking was used. The phones were fed with unfiltered square-wave pulses of 100 µs duration. The evoked potentials were picked up with gold-plated surface electrodes applied to the forehead (position Fp_z) and over the mastoid processes, and recorded between the forehead and the ipsilateral ear (with regard to stimulation). The electrode on the contralateral side was connected to ground. The impedance of each electrode pair was checked to be less than 5 kΩ.

The auditory brain-stem responses to 2000 clicks were amplified, filtered and, after static artifact rejection, recorded and averaged in a 10 ms window opened by the stimulus signal. The responses were recorded when stimulating each ear at intensity levels of 90dB, 70dB, 50dB and 0dB ref nHL (normal Hearing Level) (i.e. dB above the laboratory reference zero level). To check the replicability of an averaged response, two averages were recorded at each stimulation level and superimposed. All averaged responses were stored in computer files for digital filtering, processing, analysis and further follow-ups. The input signal from the patient was continuously monitored, to check for disturbances on the recording due to motoric hyperactivity, dislocation of electrodes, etc.

An ABR-pattern normally consists of a series of positive/negative waves within the first 10 ms after the onset of acoustic stimulation. Forehed (vertex) positive peaks are recorded as upward deflections and designated by the roman numerals I, II, III, IV, V (Jewett & Williston, 1971).

On analysis an ABR-peak was looked upon as significant only if its absolute latency (from onset of stimulation) was replicated with a latency difference not exceeding 0.1 ms. The absolute latencies and amplitudes of accepted peaks were measured, as well as identifiable inter-peak intervals I–III, I–V and III–V. Abnormalities such as absence of peaks, pathology of absolute latencies or inter-peak intervals, right–left differences and abnormal stimulus–response functions were judged according to our normative data and the hearing of the subject.

Doubtful abnormalities were disregarded. The auditory brain-stem responses were thus classified as pathological only if one or more peaks were lacking; or if the right/left difference in latencies for the identified peaks exceeded 0.2 ms at a stimulation level of 70dB, or if the latency for peak V exceeded 6.3 ms on either side.

Computed tomography

Lateral ventricular size was determined from CT scans by use of an EMI CT 1010 Scanner: slices were taken, without contrast enhancement, every 10 mm from vertex to foramen magnum. The slice showing the ventricles at their largest was selected, and the area of the lateral ventricles and of the intracranial space in the chosen cut was measured with a planimeter on the transparent film. The ventricular area was then divided by the intracranial area to provide the ventricular/brain ratio (VBR), which has been shown to correlate well with computer-derived ventricular volume (Penn *et al*, 1978). Four measurements were performed for each cut, and the mean values are presented in Table I.

Results

Ten out of the 20 patients studied exhibited abnormal auditory brain-stem responses. Two pathological brain-stem responses are presented in Figures 1 and 2: Figure 3 shows a normal ABR-pattern for comparison. The normal response pattern (patient no. 5) shows the peaks I-V, clearly identifiable, with normal latencies and normal amplitude ratios,

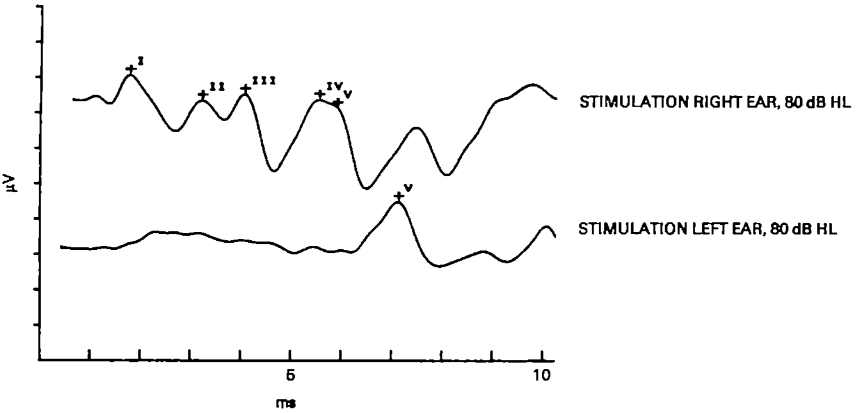

FIG. 1 Abnormal auditory brain-stem response with only a pathological delayed peak V on stimulation left. No ABR abnormality on equivalent stimulation right (patient No. 12).

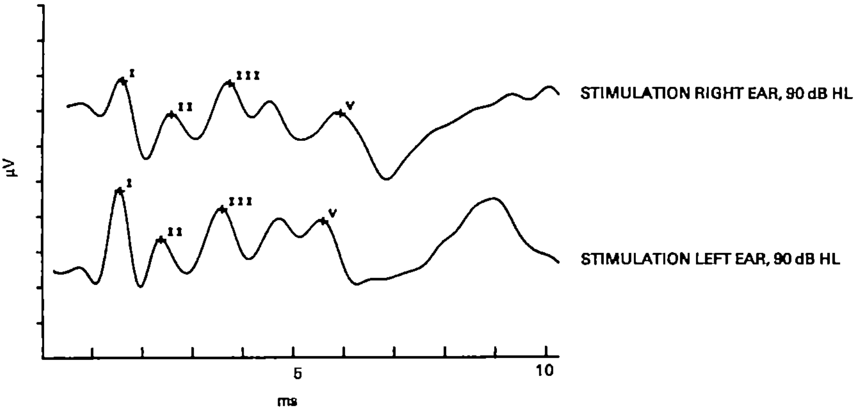

FIG. 2 Abnormal auditory brain-stem response in the form of pathological right–left latency differences (patient No. 8).

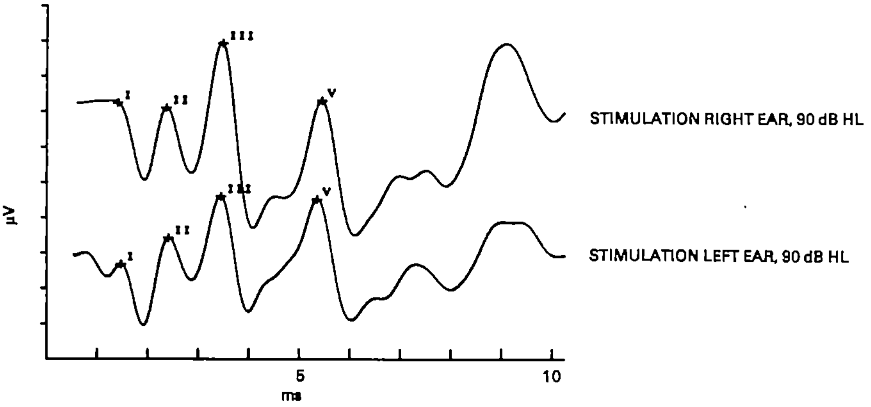

FIG. 3 Normal auditory brain-stem response in a schizophrenic patient (patient No. 5).

and without any significant right/left differences. Figure 1 (patient no. 12) demonstrates a normal response to stimulation of the right ear, but left-ear stimulation produced only a peak V with an abnormal absolute latency. In Figure 2 there is a significant right/left difference in latency of the peak II–V (patient no. 8).

There was no statistically significant difference between patients with normal *vs* abnormal ABR with regard to age ($t = 1.19$, NS), degree of psychopathology as assessed by total CPRS scores ($t = 0.53$, NS), or signs of cerebral atrophy as indicated by VBR ($t = 1.10$, NS). Nor was there any significant difference between the sexes: 7 of the 12 males (58%) and 3 of the 8 females (38%) exhibited abnormal brain-stem responses. The distribution of abnormal *vs* normal brain-stem responses within each sub-group of schizophrenia did not yield any differences between sub-groups (disorganised 3:4, paranoid 3:3 and undifferentiated 4:3).

Of the eight first-admission drug-naive patients, five (63%) displayed abnormal brain-stem response.

Although no relationships were seen between ABR and degree of psychopathology or sub-group of schizophrenia, a significant relationship was found between the presence of auditory hallucinations and abnormal brain-stem responses. Of the eleven patients who admitted having auditory hallucinations, nine had abnormal brain-stem responses. Among the nine patients who denied having hallucinations, only one had abnormal responses (Fisher's exact probability test; $P < 0.01$).

Discussion

Auditory brain-stem evoked response recording is a computerised, non-invasive tool for tracing brain-stem pathology that may cause disturbances of the auditory pathways.

The pattern of the ABR in a normal adult population is very stable, both in and between individuals (Jewett & Williston, 1971). The ABR is not significantly affected by sleep, wakefulness, psychic tension, awareness of stimuli or focus of attention: thus the ABR is characterised by a high degree of integrity, replicability and objectivity, within narrow limits of normality.

It is generaly agreed that peak I of the ABR derives from the activation of the acoustic nerve, whereas peaks II-V originate from the brain-stem, peak V being the most prominent and identifiable component of the response. Attempts have been made to establish a relationship between the components of the response and anatomical structures in the primary ascending auditory pathways (Stockhard & Rossiter, 1977), but most investigators believe that each peak reflects a composite activity of several neural structures (Jewett, 1970; Picton *et al*, 1974; Starr & Hamilton, 1976). In psychiatry, the very few ABR studies reported have dealt with autistic children (Sohmer & Student, 1978) or retarded adults (Squires *et al*, 1980). Schizophrenic patients have been studied by Pfefferbaum *et al* (1980) and Szelenberger (1983) but these studies yielded no significant findings in relation to the disease, possibly because the questions they asked and consequently the methods they used were different from ours.

The abnormal brain-stem responses reported here could not be ascribed to peripheral hearing impairment and were not related to sex or age. The fact that abnormal brain-stem responses were seen in five out of eight first-admission patients who had never received neuroleptics indicates that ABR pathology may be associated with the disease itself. However, it is well established that long-term neuroleptic medication can induce irreversible neuronal dysfunction within the basal ganglia manifesting itself as tardive dyskinesia (Gunne *et al*, 1984). Consequently, it is still possible that neuroleptics may influence the auditory pathways of the brain-stem. We have therefore initiated longitudinal studies of patients treated with neuroleptics and exhibiting a normal ABR prior to the treatment.

Our data do not support the hypothesis that the ABR pathologies were manifestations of a generalised cell loss in the central nervous system which would make itself evident in the form of enlarged lateral ventricles. The VBR *has* been found to be increased in a large proportion of schizophrenic patients (Johnstone *et al*, 1976; Weinberger *et al*, 1979) but in the present study VBRs did not differ between patients with and those without abnormal brain-stem responses. However, the sample was too small for definite conclusions. The same reservation applies when considering a possible genetic influence as a causative factor for the brain-stem response abnormalities. Three of the four patients with a family history of schizophrenia exhibited an abnormal ABR, a finding that deserves further attention in future studies.

A notable finding was the significant correlation between the presence of auditory hallucinations and abnormal auditory brain-stem responses. This observation indicates that auditory hallucinations may have an organic backround. One could speculate whether a dysfunction of the brain-stem might in some way generate impulses (like in denervation supersensitivity) which would be experienced as voices by the patient.

The different abnormalities noted in the ABR patterns of our schizophrenic patients do not permit firm conclusions to be drawn with regard to the anatomical localisation of the brain-stem pathology. In a postmortem study by Fisman (1975), encephalitic lesions with glial knots and perivascular infiltration were found in the brain-stem area in six out of eight schizophrenic patients but only one out of 24 controls. A significant role of the brain-stem function in schizophrenia has been suggested by studies on local cerebral metabolism using regional cerebral blood-flow recording (Ingvar & Franzen, 1974; Franzen & Ingvar, 1975; Mathew *et al*, 1981). It has been hypothesised that schizophrenics suffer from an abnormal distribution of activity within the brain due to an inability of the brain-stem and limbic mechanisms to activate the frontal lobes (Ingvar 1976; Weinberger & Wyatt, 1982). Such a deficiency might be caused by a sub-cortical dopaminergic dysfunction (Buchsbaum *et al*, 1982).

The present study is the first step by our group towards a more comprehensive mapping of the auditory brain-stem evoked response in psychiatric disorders, especially schizophrenia. Questions yet to be considered are whether abnormal ABR varies systematically with the clinical picture; and whether ABR is influenced by medication with neuroleptics or with the opiate antagonist naloxone, which has been demonstrated to reduce auditory hallucinations in schizophrenics (Gunne *et al*, 1977; Picar *et al*, 1982).

Asymmetry of Lateralised Hemispheric Functions in Schizophrenia
Influence of Clinical and Epidemiological Characteristics on Quality Extinction Test Performance

SILVIO SCARONE, CARLO LORENZO CAZZULLO and ORSOLA GAMBINI

The Quality Extinction Test was used to detect lateralised abnormalities of hemispheric functions in schizophrenic patients. Course of illness significantly affected the distribution of tactile extinctions, chronic patients showing more left-side extinctions than sub-chronic ones. Age significantly affected the number of left extinctions, and sex the number of right extinctions. The importance of clinical and epidemiological characteristics of the patients in determining the quality and degree of hemispheric dysfunction in schizophrenia was confirmed.

In recent series of papers (Scarone *et al*, 1981, 1982, 1983) we reported the initial findings on various aspects of tactile 'losses' in schizophrenic patients. The Quality Extinction Test (QET) (Schwartz *et al*, 1979) provided the means for assessing their tactile sensitivity, by evaluating a blindfolded subject's verbal answers to simultaneous brushing of the palm of each hand with two different common materials. In general, compared with normal controls, schizophrenic patients have been found to have a significantly higher incidence of left extinguishing responses to the QET and a greater number of left and right extinctions; in the case of the latter, the left extinctions were significantly more frequent than the right ones (Scarone *et al*, 1981, 1982). Given the organisation of the neurofunctional pathways of tactile sensitivity (Critchley, 1953), these results suggest that both the parietal and anterior frontal regions of the brain might play a role in the pathophysiology of losses in tactile sensitivity.

A possible influence of the age of the schizophrenic patients on the proportion of left extinctions was also found, in contrast to the controls; there was no relationship between QET performances and the clinical paranoid/non-paranoid dichotomy (Scarone *et al*, 1983). Although the findings are not entirely consistent, recent reports lend support to the existence of a relationship between some of the clinical and epidemiological characteristics of schizophrenia and hemispheric malfunctioning (Gruzelier, 1984; Andreasen *et al*, 1982; Luchins *et al*, 1981). Consequently, it seems reasonable to assume that characteristics of schizophrenia itself might have a determining role, relative to the nature and degree of hemispheric malfunctioning in this disorder. The objective of the present study was to further examine the QET performances of a sample of schizophrenic patients controlled for sex, age, diagnosis, and course of the disease.

Method

The subjects were 136 patients with a diagnosis of schizophrenia; Table I shows their epidemiological and clinical characteristics. The diagnosis of schizophrenia, subtype classification, and chronicity characteristics were independently determined by two senior psychiatrists using DSM–III criteria. All the patients were right-handed, as assessed by means of a standardised questionnaire (Raczkowski *et al*, 1974). Patients aged over 55 were excluded from the study, since both extended hospital stay and long-term treatment with psychotropic drugs have been reported to exercise a significant influence on hemispheric functioning (Luchins *et al*, 1981; Serafetinides, 1973). The majority (79) of the subjects were aged 18–35; the remaining 57 were aged 36–55. The 112 chronic patients tended to be older than the 24 sub-chronic patients, their mean ages being 35.8 years and 21.2 years respectively.

TABLE I
Clinical and epidemiological characteristics of schizophrenic patients, categorised according to diagnosis

Sex	*Disorganised*		*Paranoid*		*Undifferentiated*		*Total*

Chronic	15	2	7

1. $\chi^2 = 7.88$, d.f. $= 2$, $P < 0.025$
2. $\chi^2 = 8.58$, d.f. $= 2$, $P < 0.025$

None of the patients had a history of brain damage, and all had negative findings on physical and neurological examinations before administration of the QET. All subjects had been receiving medication (phenothiazines or butyrophenones) for at least six months before the study and up to the time of QET testing. The QET was administered in accordance with the standard procedures (Schwartz *et al*, 1977). The total QET score was derived by subtracting the number of negative responses relating to the more accurate hand from that relating to the other, and expressing this difference as a percentage. The absolute number of left and right extinctions was also computed.

The distribution of left and right extinctions was tested by 2 × 2 and 2 × 3 contingency tables. A linear stepwise multiple regression analysis was performed, with the number of left and right extinctions as the dependent variables and age, sex, diagnosis, and chronicity as the independent ones.

Results

Table II shows the distributions of tactile extinctions according to age, sex, diagnostic categories, and chronicity. Chi-squared tests showed no significant relationships to the first three of these. The course of schizophrenia, however, does affect the extinction distribution: chronic patients show significantly more left extinguishing characteristics ($P < 0.025$). To check for the possible influence of age on this relationship, 24 chronic patients were age-matched with a sub-group of 24 sub-chronic patients. The results are also given in Table II; once again there is significant relationship between chronicity and tactile extinction type ($P < 0.025$).

When multiple regression analysis was performed, taking the number of left and right extinctions as dependent variables and age, sex diagnosis, and chronicity as independent variables, age was found to be the only independent variable affecting the number of left extinctions (R-square $= 0.470$, F-test $= 6.651$, $P < 0.025$). The insertion of the other variables into the regression equation did not significantly increase the proportion of variance accounted for. The multiple regression analysis relating to the number of right extinctions showed that sex was the only independent variable which increased the proportion of variance accounted for (R-square $= 0.703$, F-test $= 10.209$, $P < 0.001$).

Discussion

Degree of chronicity appears to be the clinical characteristic most markedly related to the distribution of tactile extinctions in the group studied, with the more chronic patients having far less left tactile sensitivity. Since the same differences appeared when age-matched subjects were compared, this finding seems to be unrelated to patients' age.

The relationship between chronicity and left tactile abnormal sensitivity might be interpreted in a variety of ways, but from the anatomico-functional viewpoint it would seem to reflect a specific impairment in hemispheric functioning – one inherent in the ongoing course of schizophrenia. Furthermore, this hypothesis is consistent with findings from other studies that have demonstrated a significant direct relationship between chronicity and degree of cerebral malfunctioning (Johnston *et al*, 1976; Gruzelier, 1984). Within this anatomico-functional context, there is also the possibility that other factors closely related to duration of illness, such as the length or number of admissions or exposure to pharmacological treatment, might affect tactile sensitivity. All these factors have been shown to have an influence on hemispheric functioning in schizophrenia (Luchins *et al*, 1981; Serafetinides, 1973).

The results reported here did not replicate a previous finding of a significant direct relationship between age and the incidence of left extinctions (Scarone *et al*, 1982). This might be explained, however by the fact that patients over 55 were not excluded from the previous study group; that group included a number aged over 60, all of whom had a marked tendency to be left extinguishers. The finding that there is no relationship between subtype of schizophrenia and the distribution of extinctions is consistent with results from an earlier and smaller sample (Scarone *et al*, 1983).

It is possible to conclude that QET responses in schizophrenia are independent of the clinical aspects of the illness and are related instead to some type of neurofunctional impairment in hemispheric functioning that is inherent in the disease itself. Since other neuropsychological and psychophysiological measures of lateralised malfunctioning show the same characteristics (Gur, 1978; Gruzelier & Hammond, 1980). It can be suggested that some hemispheric abnormalities reflect a certain degree of nuclear pathology in schizophrenic patients.

In schizophrenia, the quantitative aspects of tactile extinctions appear to be quite different from their qualitative ones; in fact, the present results show that patients' age significantly explains a part of the variance in the number of extinctions. Data from the neurological literature suggest that the left-sided pathways of tactile sensitivity are more vulnerable than the right-sided ones (Schwartz *et al*, 1979). The possibility thus exists that some age-dependent neurofunctional modifications in hemispheric assessment play a critical role in determining such vulnerability.

The finding that patients' sex explains a part of the variance in the regression equation for the number of right extinctions does not lead to any simple interpretation, and needs to be evaluated in the light of additional data. According to the neurofunctional interpretation of the tactile sensitivity pathways, however, a high rate of right-side extinctions almost exclusively reflects malfunctioning of the left hemisphere. A recent clinical study demonstrated that neurological lesions of the left hemisphere differentially affect males' and females' lateral functioning (Inglis *et al*, 1982), thus suggesting that sex has a marked effect on hemispheric functional organisation. It is therefore possible that lateral functional disorders, as well as anatomical lesions, might be sex-dependent where such organisation is concerned.

The *R*-square values obtained explain a small part of the variance in both of the regression analyses undertaken. Other variables that were not introduced into the equation, such as duration and number of hospital admissions or duration of psychopharmacological treatment, might be important in determining QET responses in schizophrenia. Only continued study, however, will allow greater understanding of tactile sensitivity and its precise relationship to schizophrenia.

Correlates of Suicide Attempts and Ideation in Schizophrenia

J. LANDMARK, Z. Z. CERNOVSKY and H. MERSKEY

A group of 118 patients with a hospital diagnosis of schizophrenia was reviewed. The incidence of suicide attempts was significantly correlated with more frequent past psychiatric admissions, more frequent past diagnoses of schizophrenia, and poor work function. The apparent relationships could be spurious or based on a reversed causal sequence; for example, suicide attempts are likely to be followed by psychiatric admissions.

Although it has been estimated that about 10% of patients with schizophrenia commit suicide (Miles, 1977), little is known about the clinical characteristics of those schizophrenic patients who are most at risk of such an outcome (Wilkinson, 1982). The sparse data available suggest that important features associated with suicidal tendencies may include: feelings of depression or a known history of depression and unemployment (Roy, 1982), episodes of excitement with acute panic or protracted anguish (Planansky & Johnston, 1973), an extensive history of past psychiatric admissions (Roy *et al*, 1984), and in some cases an increased ventricle: brain ratio (Levy *et al*, 1984). Research involving a larger spectrum of possible predictors is needed both in respect of schizophrenic symptoms, such as anhedonic features or persecutory delusions, and of demographic, social, and anamnestic variables.

The present study examined the relationship of both suicidal behaviour and ideation to 143 variables, including anamnestic and sociodemographic variables, symptoms relevant for clinical assessment or research in schizophrenia, and the patients' diagnoses according to 12 systems for diagnosing schizophrenia, as outlined by Landmark (1982).

Subjects

One hundred and eighteen patients (46 men, 72 women) of the London Psychiatric Hospital in London, Ontario, participated; they were drawn from 120 patients examined in a series of studies (Cernovsky *et al*, 1985; Landmark *et al*, 1986). The mean age was 38.4 years (s.d. = 9.8). All had been diagnosed as schizophrenic at least once in hospital settings in the past, and all were classified as schizophrenic by at least one of the 12 systems for diagnosing schizophrenia described by Landmark (1982). At the time of assessment, all patients were stabilised on major tranquillisers for at least 12 months and were currently being treated with fluphenazine decanoate.

Method

The assessments were carried out on an individual basis by means of a diagnostic checklist and ratings described by Landmark (1982). The ratings provided the basis for the diagnosis according to 12 leading systems for diagnosing schizophrenia, while still another diagnosis was added by using Bleuler's (1920, 1950) system, with a cut-off score of three instead of four of his four criteria. The checklist also included quantitative information on a variety of sociodemographic and anamnestic variables: those included in the present study have been described in more detail by Cernovsky *et al* (1985). Ratings for all variables were based on interviews with patients and relatives as well as on data from hospital files.

Suicidal tendencies were retrospectively scored as follows: no suicidal thoughts or attempts (1); suicidal thoughts – rarely (2); suicidal thoughts – frequently (3); attention-seeking attempt – once (4); attention-seeking attempt – twice or more (5); serious attempt – once (6); and serious attempt – twice or more (7). The questions employed in conjunction with this scale are given by Landmark (1982). An alternative grading system was also created for suicidal attempts: no known history of suicidal thoughts or serious attempts (1); serious attempt – once (2); serious attempt – twice or more (3). The data for the latter grading system were examined for a subsample of patients (20 men, 39 women; mean age = 40.7, s.d. = 10.1 years) after patients with known suicidal ideation or attention-seeking attempts, but free of serious attempts, were excluded. This variable was defined to study the associations of serious suicide attempts independently of the confounding element of possible attention-seeking bahaviour.

The magnitude of the relationships of our two key variables – suicidal tendencies and suicide attempts – to diagnostic, anamnestic, and sociodemographic variables was evaluated by means of Kendall's tau. The analyses were exploratory: only a few expectations were held, and more than 200 relationships were examined. The criterion of significance was set at the 1 in 100 level (two-tailed).

Results

Serious suicide attempts were known in 27 patients (23%), and 14 (12%) had made repeated attempts. Attention-seeking suicidal behaviour was observed in 25 patients (21%), less than half of whom (11 patients) had made repeated attempts. Thirty-four of the remaining 66 patients (29% of the total sample) had a known history of suicidal ideation: the thoughts with suicidal content were rated as frequent in

TABLE I

*Correlates of suicidal tendencies and attempts, using Kendall's tau**

Correlate	*Suicidal tendencies (n = 118):τ*	*Suicide attempt (n = 59):τ*
Number of admissions for psychiatric problems	+0.27**	+0.42**
Number of times diagnosed as schizophrenic in the past	+0.23**	+0.35
Over-reaction to anxiety[1]	−0.23	
Present abuse of marijuana[2]	+0.23	
Mood alterations and fluctuations	+0.22	
Poor work function[3]		+0.35
Number of different addresses	+0.22	+0.34

*Only coefficients significant to $P < 0.01$ (2-tailed) are listed; $^{**}P < 0.001$. Information was not available for all patients on some of the variables, hence apparent inconsistencies in significance levels.

1. Coded: yes = 1, no = 2. 2. Coded: none = 0, 1–3 times/month = 1, 1–2 times/week = 2, more than twice/week = 3. 3. Coded on a scale of 1 to 4; 1 = good, 4 = poor (Landmark, 1982).

22 of these (19% of the total sample). Only 32 patients (27%) were free of a known history of suicidal ideation or attempts.

Only a few of the relationships evaluated were significant (Table I). The number of past hospital admissions was found to be the most salient marker for both suicide attempts ($\tau = 0.42$) and for suicidal tendencies ($\tau = 0.27$). In general, the results suggest that chronic patients may be more likely to show frequent suicide attempts or tendencies: they were more frequently admitted to hospital and diagnosed as schizophrenic, and had longer histories of schizophrenic symptoms. The work functioning of those who attempted suicide was poorer. Suicidal tendencies were associated with over-reaction to anxiety, mood fluctuations, and with a history of marijuana use. The first of these suggests impulsive maladaptive ways of dealing with anxiety-provoking situations. Marijuana use has similarities to suicidal tendencies, in that both can be forms of avoiding more direct coping with reality.

Suicide attempts or tendencies were unrelated to the incidence of other symptoms and to other sociodemographic, anamnestic, or diagnostic variables, including the diagnoses according to all the systems for diagnosing schizophrenia. No relationships were found to age, gender, or educational level.

Discussion

The findings of more frequent past psychiatric admissions, frequent changes of address, and over-reaction to anxiety confirm the reports of other investigators (Planansky & Johnston, 1973; Roy, 1982; Roy *et al*, 1984). However, in contrast to findings by Roy (1982), no significant relationship of suicide attempts or tendencies to the incidence of depressive symptoms (item 138 in Landmark's (1982) diagnostic checklist) was found in our analyses. Similarly, in contrast to a study by Brier & Astrachan (1984), no relationships were found to age, gender, or marital status, and in contrast to a study by Drake *et al* (1984), the educational level did not emerge as a significant risk marker. Further research is needed on this point.

Suicidal behaviour in schizophrenic patients is a major problem: 44% in our sample and 55% in the sample studied by Roy *et al* (1984) had a history of suicide attempts. This is probably not limited to our samples or to North American settings; for example, Hessø (1979) reported similar findings in Norway. There is some evidence that suicide rates in psychiatric patients, especially in functional psychoses, may have been rising in the last two decades (Hessø, 1979; Retterstøl, 1978). It is therefore important to identify predictors of suicidal risk. However, our search for such predictors is obstructed by an unexpected methodological problem: our most salient potential predictor was chronicity, in terms of repeated psychiatric admissions and repeated diagnoses of schizophrenia. Although this is consistent with past research, the variable is not necessarily a valid predictor of suicidal risk. The relationship could be spurious, or could be interpreted in a manner which reverses the causal sequence. Suicidal ideation and attempts may be more likely to be known for patients with more sustained contact with psychiatric institutions, simply because more information about the patient is likely to accumulate. The time span involved may be a confounding factor both in our findings and in those reported by Roy *et al* (1984).

If chronicity is an important factor, the correlation coefficients for the relationships of suicidal tendencies (or suicide attempts) to the duration of the longest stay in hospital and to the total number of months in hospital should be positive and significant. In our study, the coefficients involving these variables were close to zero and not significant (Pearson's $r = 0.02$ and 0.14 respectively for suicidal ideas, and $r = 0.01$ and 0.05 for serious suicide attempts).

Another manner of demonstrating the confounding variable is to examine the coefficient found between suicidal tendencies and chronicity of symptoms. A partial correlation coefficient computed for the relationship of the two variables, with control for the number of psychiatric admissions, was not significant at the level set ($r = 0.02$, $P = 0.038$, 2-tailed). The same was found with a coefficient controlled for the number of times the patient was diagnosed as schizophrenic ($r = 0.21$, $P = 0.027$, 2-tailed). Because of the nature of the study, we have required a more stringent level of significance than would otherwise be necessary; a replication study need only find a probability of 0.05, 1-tailed, in order to support the hypothesis .that chronicity has a relationship with suicide, notwithstanding the artefact which length of illness may produce. In fact, since there were several other findings which were all significant at a level of 1 in 1000 which related to suicidal tendencies or to suicide attempts and which arise from chronic effects, it seems likely that there is a true relationship between chronicity and suicidal tendencies or suicide attempts, notwithstanding some of our negative evidence.

It should also be noted that our key variable, the serious suicide attempt, is likely to be followed by re-admission, and thus these attempts are antecedents rather than consequences of the number of admissions. Hence, the causal sequence is reversed. To defend the opposite viewpoint, however, it may further be pointed out that a history of past suicidal attempts (or of ideation) is a good predictor of suicidal risk, at least in other populations (McCourt & Solomon, 1974).

Difficulties of interpretation associated with our study and with other past studies could be avoided if, for all patients in a sample, the time span during which the attempts are recorded were to be held constant. For example, chronic and less chronic patients could be compared, in a retrospective or prospective design, in respect of the incidence of suicide attempts within a specific time span such as two years. It is possible that chronicity, or the number of past hospital admissions and other related variables such as previous history of suicide attempts, would then be shown to be risk markers.

The main contribution of this study is thus the confirmation of the association of frequent admissions to psychiatric hospitals with the incidence of suicide attempts or tendencies in schizophrenia, and in demonstrating that this finding could be spurious or based on a reversed causal sequence, i.e. that suicidal attempts are followed by admission.

Suicide and Social Response in Fiji: A Historical Survey[1]

RUTH H. HAYNES

A historical review of suicide in Fiji shows that rates for people of Indian descent have always been higher than those of other groups, yet until now this phenomenon has attracted little official or public attention. Recent changes in the incidence and methods of suicide have led to the introduction of some preventive measures, but the emphasis has been on eliminating some of the methods rather than the reasons for suicide. The continuing high incidence of suicide by hanging involving some sectors of society appears to have been overlooked. Possible causes of this apparent lack of interest are examined, such as the low status historically of Indian immigrants and concepts held about them by other groups in Fiji, and the 'invisibility' of groups of people such as rural women and the aged.

In a study of suicide in Macuata, Fiji during the period 1979–82, the circumstances of suicide were discussed (Haynes, 1984). The present study examines the social and official response to this phenomenon over a 100-year period and attempts to define the factors which have shaped that response.

Historical background

Indians were first brought to Fiji under the Indenture system, which was introduced in 1879 and ended in 1920: this followed the pattern already established in the Caribbean, South Africa, and Mauritius to provide cheap labour for the sugar industry. The abuses of the Indenture system have been well documented both by contemporary writers (Andrews & Pearson, 1916) and by modern historians (Tinker, 1974; Gillion, 1962; Ali, 1979). In most respects the conditions of Indenture were little better than those of slavery, except that the contract (or 'indenture') was for a limited period of five or ten years. In principle at least there was an end in sight, even if in practice many did not survive the system.

High suicide rates were acknowledged as early as 1871, when Sir Arthur Gordon (successively the Governor of Trinidad, Mauritius, and Fiji) commented in a letter to Lord Kimberley on "the extraordinary frequency of suicide amongst Indian immigrants of this colony"; he was referring here to Mauritius, but the comment was equally true of other territories. This high rate he attributed to a low ratio of female to male immigrants, leading to rivalry and jealousy and to "nostalgia and the intense desire to return to India" (Tinker, 1974).

Suicides were frequently recorded at the first stage of recruitment, when Indians were collected in large depots at the ports of Calcutta and Madras and the realisation of what recruitment meant dawned on them – especially for the many who had been recruited fraudulently. As Andrews & Pearson (1916) recorded: "Many throw themselves into the Hughli to escape the emigrant ships". Interviews with those who had experienced the Indenture system showed that many had no idea that the contract involved travel overseas, and some were merely escaping minor problems in their villages or were seeking work in India itself (Ali, 1979; Naidu, 1980).

Sea voyages from India to various destinations in the Caribbean and Pacific might last 3–6 months, and the physical hardships associated with these voyages have been compared with the middle passage of slavery. Some emigrants threw themselves overboard during the voyage, overcome by despair and in many cases by the fear engendered by crossing the ocean, which meant defilement and loss of caste for Hindus. Commenting on these suicides, a medical officer in charge of one voyage in 1873 declared: "This amusement is getting rather too common" (Tinker, 1974). He was later dismissed, but his comment reflected, to some extent, contemporary attitudes towards emigrants. Disease was rife on these voyages and mortality rates high, but measures taken to control disease were motivated more by economic considerations than by thought for the well-being of the emigrants.

After arrival at their destinations, many more Indian emigrants committed suicide. "Of all aspects of sickness and mortality on the plantation, the most sombre was that of suicide. . . In the depression of the

---

[1] Based on a lecture presented at the spring Conference of the British Medical Anthropology Society, March 1985.

P 25, 4 21

first year or two of indenture many sought to end their existence" (Tinker, 1974). Suicide figures for Fiji were particularly high compared with India itself and with other colonies where the Indenture system existed. Andrews & Pearson (1916) give suicide rates for Madras of 4.6 per 100 000 and for the United Provinces of 5.4 per 100 000; these were the main areas of recruitment. For Natal the figure was 64 per 100 000, and for Fiji they gave figures of 78 and 83.1 per 100 000 for the years 1903 and 1910 respectively. By 1915 rates in Fiji had reached a peak, and Andrews (1915) wrote in a letter to Lord Hardinge that "one in every 900 indentured coolies committed suicide – one in every 900!"

Drawing on statistics from the Fiji Royal Gazette, Naidu (1980) showed that the incidence of suicide was high in 1902–03 and again from 1911–15. In 1912 there were 18 suicides recorded among 15 369 indentured workers, in 1913 there were 20 among 15 961, and in 1915 there were 18 among 14 326, all giving rates of around 120 per 100 000. Some of these periods coincided with an influx of workers from South India, recruited in Madras, who often felt isolated in a society dominated by workers from North India. The Immigration Department of Fiji commented: "For what appeared to be inadequate reasons, Madrasis appeared to be prone to suicide and depression when placed among Northerners" (Gillion, 1962).

The Indenture system was characterised by violence of all kinds, and Fiji's reputation was seen as worse than most. Ali (1979) and Naidu (1980) interviewed over 40 elderly Indians who had been recruited, and graphic accounts were given of violence between employers and workers, and between workers themselves; of murder, manslaughter and suicide. Many mentioned the disproportion of the sexes (the male:female ratio was 3:1 in Fiji) as a major cause of violence, leading to constant rivalry and jealousy. But the general conditions which generated despair and nostalgia, the loss of intimate shipboard friends, ill treatment by those in authority, overwork, illness, sheer weakness, and exhaustion all contributed to suicidal tendencies.

It is likely that suicide and other forms of violence were under-recorded, workers fearing reprisals if crimes were reported and also having little faith in the current system of justice. From the planter's perspective it was in his interest to "hush up serious crime on his estates... The temptations to hide facts which might tell against the system must have been great indeed" (Andrews & Pearson, 1916). Planters maintained that workers were content with the lowest conditions, which were in practice often attributed to the Indians' alleged inferiority rather than to plantation mismanagement. "The moral degeneration of the 'lines' was seen by the planters and overseers as a reflection of the character of the recruits and the class they came from in India" (Naidu, 1980).

The stereotyping of Indians by contemporaries was almost invariably negative. Planters and administrators could best justify the system by denigrating the Indian character, and such stereotyping lasted long after Indenture ended. Native Fijians were also hostile; fears that Indians would eventually outnumber them were expressed by the Great Council of Chiefs in 1888: "The Indians in course of time will bring about a change in the manners and customs of our land... and will stamp us out... Presently we shall be blotted out by the number of these people who keep coming. Let them go back to their own country when they have finished their work" (Gillion, 1962). Today Indians outnumber native Fijians and are the largest ethnic group in Fiji. As such they may still be seen as a political and economic threat to Fijians, a factor not always conducive to harmony.

Figures are lacking for the period 1920–1960, but the consistency of later findings suggests that Indian suicide rates have continually been high, even though the reasons may have changed. Certainly the legend appears to have evolved that Indians are prone to suicide; this may well have affected the perceptions of the public and of officials such as coroners.

It should be noted here that Indian society in Fiji is far from homogeneous. 'Indian' usually means the Hindi-speaking descendants of emigrants from North-eastern India; occasionally it includes Tamils and Telegu from Southern India, Muslims, and Gujeratis (Jayawardena, 1980). Gujeratis, Sikhs and Punjabis all came to Fiji after the Indenture period, and their descendants today dominate the commercial life in major towns. Records kept by police and medical departments do not normally distinguish between these groups which are all classified as Indian. In this context ethnicity alone may be much less important than differences in culture and customs associated with these groups.

Suicide today

Studies dating from the early 1960s are consistent in showing that Indians are over-represented among suicides in Fiji, accounting for approximately 90% of all victims where they comprise just over 50% of the total population. The studies cover the periods 1962–68 (Ree, 1971), 1971–1972 (Karim & Price, 1973), and 1979–82 (Haynes, 1984). Those by Ree and Haynes were based on police records in

Macuata; that by Karim & Price was based on medical records for all of Fiji.

In all three periods suicide was found to be associated with Indian descent, Hindu faith, rural residence, youth (especially of females), joint family units (i.e. the extended family living in one homestead), an absence of diagnosed mental illness, and interpersonal conflict within the family. In all three periods hanging was the commonest method of suicide, accounting for 95% and 92% of all cases in the two earlier periods and for 74% in 1979–82; in all periods a larger percentage of women than of men died by hanging. The greatest changes in the past twenty years have been in the total number of recorded suicides (an increase of 80% since 1972, compared with a population increase of 19%), and in a change of method.

The studies by Ree (1971) and Haynes (1984) were conducted in the rural province of Macuata, and were based on police records of unnatural deaths which had received verdicts of suicide in the Magistrates' Court. These studies were comparable with respect to the total number of suicides, the distribution by age, sex, and ethnic origin, and also to the circumstances of suicide. In 1962–68 only 4 out of 73 suicides were by non-Indians, and in 1979–82 only 3 out of 69 (in Macuata province 75% of the population is of Indian origin).

In both periods, 82% and 83% respectively of female suicides were under the age of 30, and almost all of these died by hanging. Samples were generally too small for age-specific rates to have any significance, but in both periods there was a larger than expected number of Indian women aged 15–30.

Haynes (1984) gave the following rates per 100 000 for Indians in Macuata: males aged 10–29 years, 36.1; females aged 10–29 years, 74.8; males aged over 30 years, 70.5; females aged over 30 years, 28.2. This shows that young women and older men were particularly at risk of suicide. This is in contrast to rates for Fiji as a whole, where the rate for all Indian women in 1981–82 was only 33.1 per 100 000 and for all Indian men 45.2 per 100 000 (Table I).

Conflict within the family particularly between parents and children, and between young married women and their in-laws, appeared to be a major precipitating factor among female suicides. Childlessness was noted in 14 out of 28 married women in Ree's study, and was noted as a factor by Haynes where in-laws or spouses had taunted young women for failing to produce sons.

Family conflicts also featured in male suicides, although to a lesser degree, and some suicides appear to have been precipitated by shame, debt, or fear of disgrace or failure. Among older men (aged 60–69 years), whose high rate boosted the figure for all men over 30, suicide was usually preceeded by physical or mental illness (Haynes, 1984). This is a group for whom three old peoples' homes were established in Fiji, as so many became destitute in old age when they were no longer economically useful. Even those with families could be rejected in old age, and a survey of old peoples' homes in 1974 showed this group to be particularly vulnerable (Haynes, unpublished).

TABLE I

Suicides in Fiji, 1971–72 and 1981–82 (annual rates per 100 000)[1]

Period	*Sex*	*Indians*	*Fijians*
1971–72[2]	Males	24.9	2.1
	Females	23.1	0.7
1981–82[3]	Males	45.2	9.2
	Females	33.1	9.3

1. Rates are based on the population figures given for adults (aged 15 and over) in the 1966 (for 1971–72) and 1976 (for 1981–82) censuses. Estimates suggest that populations in 1971 and 1981 are each approximately 10% greater than these figures; the rates given are therefore slightly high.
2. Karim & Price (1973).
3. Haynes (1984).

The most recent change has been in the method of suicide. Karim & Price (1973) reported that in 1971–72, 92% of all suicides were by hanging; the remaining 8% used firearms, cutting instruments or drugs. By 1979–82 only 77% of female and 69% of male suicides in Macuata were by hanging, and paraquat was beginning to be recorded as a suicide agent. This is marketed in Fiji under the name Gramoxone, and is in common use on cane farms where it is recognised as an effective herbicide, safe when used correctly and quickly becoming inert on contact with the soil. Ingestion of 10 ml (i.e. one mouthful) can prove fatal, and deaths may be painful and lingering.

Records show that between 1981 and 1985, 177 people were admitted to hospital with paraquat poisoning, only 70 of whom survived. Approximately two-thirds of the 107 who died were suicides, and most of these were Indians aged 15–30 years (Vuetivavalagi, 1985). However, police records showed that the majority of suicides were still by hanging: in 1983 there were 60 by this method, and 23 by paraquat poisoning (Royal Fiji Police, 1984).

In examining methods of suicide it is important to remember that some of those who previously attempted suicide by poisoning probably survived. Paraquat was introduced into Fiji in 1972 (under the Pesticides Act 1971), but appears not to have been abused for purposes of suicide until much later. Attempts made with less toxic chemicals were less likely to be fatal, whatever the intention, and some of these who in the past were rescued or resuscitated may in fact have intended to die.

Intention in cases of poisoning can at best only be surmised, whereas hanging is a method rarely expected to fail. Deaths from poisoning were more likely in Fiji to be followed by an inquest than those resulting from hanging. Lack of evidence has frequently led to verdicts of accidental death, even where suicide has been suspected (Fiji, 1978).

It is also possible that Coroners' verdicts might be affected by the 'legend' of Indian suicides, and that a verdict of suicide is more likely to be given to an Indian than to a Fijian where circumstances of death are similar.

Social response

The official and public response to this new phenomenon has been remarkable in contrast to the apparent acceptance shown towards Indian suicides over the past 100 years.

Attempted suicide is still an arrestable offence, and official attitudes are somewhat punitive. A police officer may arrest and send for trial any person whom he suspects of attempting or preparing to attempt suicide; the normal sentence is one of probation (Fiji Criminal Procedure Code, 1978). This legislation appears to be applied relatively infrequently; the author found that in the period 1979–82 only 15 of 65 people admitted to one hospital following a suicide attempt were actually placed on probation.

Health planners seem until now to have overlooked the question of suicide, and mental health generally received scant attention in development plans. In the Eighth Development Plan (1981–85) priority was given to physical and environmental health, sanitation, nutrition, child health, and family planning; mental health received a passing reference, and suicide none at all (Central Planning Office, 1980).

Although suicide rates for Indians have always been high compared with other ethnic groups, the recent and sudden increase in deaths due to paraquat abuse has created widespread alarm. Since 1983, when such deaths were first publicly acknowledged, a series of conferences and seminars have been devoted to this problem. Representatives of the Ministries of Health and Agriculture, the police, the Consumer Council, and of many other departments have examined all aspects of paraquat use and abuse. Controls over the importation and distribution of paraquat, the feasibility and costs of adding emetics and stenching agents, the deterrent effects of such additives, and the treatment of symptoms have all been discussed. The need for stringent controls on the sale of agricultural chemicals, using only licensed retail outlets, is universally accepted. A major problem arises when paraquat is bought in bulk and transferred by farmers into unlabelled bottles, lacking instructions as to use, precautions or antidotes. Such careless storage methods have been responsible for a number of deaths, when victims have drunk impulsively from the nearest bottle – sometimes when intoxicated.

By July 1985 paraquat deaths had become the main subject of debate in Fiji's Senate. Some senators called for a complete ban on the importation of paraquat, and others for tighter restrictions on its sale and distribution. There was also discussion on the role of the media, one senator suggesting that the publicising of suicide only encouraged others to take their own lives, and another that such reporting would have a deterrent effect (Vuetivavalagi, 1985). For the first time it was acknowledged that more people died by hanging than by poisoning, and it was humorously suggested that perhaps there should be similar restrictions on the importation of rope!

Frequent allegations have been made that pesticides banned in the USA and Europe were being 'dumped' in Fiji and other parts of the Pacific. Such allegations were firmly denied by the Registrar of Pesticides in April 1984, when he reiterated that all pesticides entering Fiji were registered and that if used correctly they constituted no danger to man. He acknowledged that "the one serious problem is intentional suicide, because you can't stop that" (Keith-Reid, 1984).

The role of the media in publicising the often horrifying consequences of ingesting paraquat cannot be ignored. From early 1983, when the first editorial warned against the dangers of paraquat, there have been numerous articles in both English language and vernacular newspapers, and in professional and regional journals. Dramatic headlines and front page coverage have ensured that the public was made aware of the problem: examples are 'Poison deaths alarm doctors' (Lakhan, 1983), '107 die from paraquat' (Vuetivavalagi, 1985), and 'Chemical war in Fiji' (Keith-Reid, 1984). Almost all suicides are reported in the press; names of victims and circumstances are given, and some articles have given detailed accounts of paraquat deaths (Fiji Times, 1984). While the intention underlying such extensive coverage may have been to educate the public, its effects appear to have been far from deterrent, especially with respect to choice of suicide agent.

Quite apart from the influence of the media, the effects of a suicide on any small community must be considerable. In 1962–68 and 1979–82 only one of 142 reported suicides took place within the urban area of Labasa; all the others occurred in farming settlements of less than 1000 people or on relatively isolated cane farms. In one such settlement there were seven suicides in four years, and there were many more in a group of settlements in a cane farming valley (Haynes, 1984). Any suicide in these areas is likely to become common knowledge and perhaps affect the actions of others under stress.

The most striking feature of social and public response has been the emphasis, to the exclusion of all else, on the topic of paraquat: its toxicity, availability and control. While attention to this problem is essential, it is apparent that other suicides pass almost unnoticed: anecdotal accounts of suicides by hanging continue to be featured in the press, but these cases appear to merit little comment.

Discussion

A number of factors may have influenced official and social responses to suicide, and possibly prevented appropriate action from being taken.

It has been seen that Indians were historically accorded low status, and that stereotyping of this group by others may be a legacy of the Indenture period. Suicide was likely to be seen as proof of instability – of inferiority, rather than as a legitimate response to appalling conditions. The causes of suicide were neglected along with other physical causes of mortality. Today the causes of suicide may have changed, but some of society's responses have not.

Fiji is a plural society, in which there has been little assimilation except at a superficial level. The association between suicide and the Indian population has become almost a legend, a possible consequence of which is the neglect by the rest of society of what is seen as a peculiarly Indian problem. There has been much comment, especially by the media, but little action.

Not only have high suicide rates been overlooked by society at large, but within Indian society the lack of homogeneity prevents one group from identifying with the problems of another. For example, the problems of the Hindu farmer may have little meaning for the Gujerati businessman or for Muslims in the city. In the same way, men (who are dominant in this society) are unlikely, for various reasons, to champion the causes of women. Although Indians today comprise the largest ethnic group, they are still a political minority and until recently have been under-represented among government officials, the professional classes and those involved in health planning. Such factors may contribute to the failure of society to address itself to this problem. Where high suicide rates appear to affect a majority or ruling group, or where society is homogeneous, rising suicide rates represent a threat to the whole society and official response may be swift and all-embracing, as has happened in Western Samoa.

Within Indian society, especially in rural areas, young women are sometimes accorded low status, as are elderly men who have outlived their usefulness economically, and there may be few representatives of these groups who can voice their problems. Recent studies have shown high suicide rates (mostly involving hanging) for these groups, yet these deaths appear to have been overlooked by those involved in the latest preventive campaigns: these are the 'invisible' suicides.

The shame and guilt traditionally associated with suicide may also create something of a taboo, which prevents comprehensive study of this subject. Families involved often wish to deny or forget a suicide, especially if it has been inferred that they were in any way responsible. Among Muslims and Christians, religious prohibitions concerning suicide may also lead to denial or to a diminished response.

In recent years the spate of paraquat deaths, whether suicidal or accidental, has focused attention on treatment and preventive methods, and society has demanded an immediate solution. Efforts have been concentrated on controlling the supply of toxic substances or even of banning them altogether, and this type of research has overtaken investigations into the causes of suicide.

Official response has also been fuelled by the international scandal over pesticides. Paraquat abuse has been reported from as far afield as Trinidad, Thailand, Western Samoa, and Malaysia where, apart from suicides, there have been many accidental deaths (Reiss *et al*, 1983). The anti-pesticides lobby has been active in Fiji as well as in other parts of the world, and its allegations have required a response – if only in defence.

It is understandable that the initial public response is to seek a solution reasonably certain of success. If it is true that people in the past attempted suicide by poisoning but survived and the availability of a new and more potent toxin has resulted in more fatalities, then perhaps the logical step is to ban that substance. Such action may be effective in preventing both accidental and suicidal deaths from paraquat, but it fails to acknowledge the majority who die by hanging. Ultimately the question that should be asked is not "How?" but "Why?"

Further studies are needed, preferably conducted by local scholars familiar with the language and culture, into all groups at risk, into the psychodynamics of family life, and into different behavioural responses to stress. Comparisons need to be made between rural and urban families and between different religious and ethnic groups. Suicide is likely to remain a major problem until the reasons underlying it are systematically studied.

A possible preventive programme might be modelled on experience obtained in Western Samoa. Until the early 1970s the incidence of suicide was around six cases/year. Between 1972 and 1982 the incidence rose steadily to a peak of 49 cases in 1981 – mostly suicides by young men who had ingested paraquat. The 1981 rate for men aged 15–24 years was 94 per 100 000 (Keith-Reid, 1983; Oliver, 1983). A major campaign was mounted to examine the reasons for suicide, and a multi-disciplinary group representing the police, the judiciary, health and education departments, churches, and villagers initiated a public awareness campaign. Public meetings were held and careful use made of the media to educate the public. Knowledge of local custom meant that media coverage was tightly controlled, as it was felt that overdramatic accounts might actually attract some youths to a test of endurance like that once provided by full-body tattooing (now forbidden by law). Such a campaign, which gives recognition to local custom, might be successful elsewhere; it has certainly been effective in Western Samoa, where only five paraquat suicides were recorded in 1984.

Little will be achieved until the communities most affected acknowledge the problem and are motivated for change. Women's organisations and Indian communities in general need to be involved in planning and to make sure they have a voice. To start with, urban and educated people who have access to such groups may be needed to represent the more isolated and weaker members of society. While these groups can help, the ultimate responsibility lies with central government to ensure that sufficient resources are allocated to the understanding and resolution of this problem.

Psychological Correlates of Unemployment Among Male Parasuicides in Edinburgh

S. D. PLATT and J. A. T. DYER

Variations in clinical features associated with unemployment among a sample of male parasuicides were examined. Employed and unemployed persons did not differ in mean scores on the Suicidal Intent Scale, but the unemployed were rated significantly worse on measures of depression (Beck Depression Inventory) and hopelessness (Hopelessness Scale). A covariance analysis showed that hopelessness, rather than depression, is the important discriminator. Different patterns of relationships between the three clinical measures were observed in the two groups. Hopelessness may be a key social-psychological variable for inclusion in any model of the pathways which link unemployment with parasuicide.

Numerous investigations carried out over the past 15 years have revealed more depression, anxiety, negative self-esteem, negative affect, psychological distress, and potential psychiatric illness among unemployed individuals, particularly men, than among those in paid employment (Warr, 1983; 1984). The cross-sectional design of the majority of these studies presents problems of causal interpretation, but there have been a number of longitudinal investigations (e.g. Banks & Jackson, 1982; Cobb & Kasl, 1977) which demonstrate the aetiological impact of unemployment on psychological well-being. Evidence of the role of joblessness as a contributory cause of severe morbidity is less convincing, but also points in the same direction. Roy (1981) found significantly more unemployment among depressed male patients than among control patients. In their community survey in London, Bebbington *et al* (1981) identified 6% of employed males as psychiatric cases, compared with 14% of unemployed males. On the basis of psychiatric interviews with 72 unemployed young Australians, Finlay-Jones & Eckhardt (1981) concluded that in 43% of those with a severe psychiatric disorder the onset followed unemployment in the absence of any other recent severe stress. In a further 23% of cases the onset of disorder also followed unemployment, but these individuals had also experienced at least one other severely stressful life event in the three months prior to onset.

Fruensgaard *et al* (1983) estimated that for 41% of their sample of 70 unemployed patients admitted to a psychiatric department in Odense, Denmark, unemployment had played an important part in their current psychiatric illness, although for only 11% was it the sole causal factor.

Strong evidence of a significant association between completed suicide and unemployment rates, both cross-sectionally and over time, is also available (Platt, 1984). One of the few studies of trends in unemployment and parasuicide (Platt & Kreitman, 1984, 1985) revealed that the risk of parasuicide among unemployed men in Edinburgh was 11 times that of men in work in the same city. Those most at risk were the long-term unemployed. Platt & Kreitman concluded that unemployment (especially prolonged) is an important aetiological factor in parasuicidal behaviour.

The present study examined variation in clinical features associated with unemployment among a sample of economically active male parasuicides (i.e. excluding students and retired persons). It is known that depression and hopelessness are significantly associated with parasuicide (Weissman, 1974; Wetzel, 1976) and with suicidal intent (Minkoff *et al*, 1973; Beck *et al*, 1975). The major question which this study seeks to answer is whether unemployed parasuicides will report more depression and hopelessness, and a higher level of suicidal intent, than employed parasuicides; i.e. will the finding of deficits in psychological well-being among the unemployed in the general population be repeated in a sample of parasuicides? A further objective is to examine the inter-relationship of hopelessness, depression, and suicidal intent within subsamples of parasuicides differentiated by their employment status. Dyer & Kreitman (1984) found that hopelessness was the essential mediating variable, correlating significantly with intent irrespective of level of depression. Their findings replicate those reported in a number of American studies (e.g. Minkoff *et al*, 1973; Beck *et al*, 1975; Wetzel *et al*, 1980). We were interested to ascertain whether these same inter-relationships were also evident in each employment status group separately.

Method

The method and subjects of this study, which was carried out at the Regional Poisoning Treatment Centre at the Edinburgh Royal Infirmary in 1979, have already been described (Dyer & Kreitman, 1984). Briefly, 120 parasuicides were interviewed, 30 in each of four age-sex groups. All cases were of parasuicidal self-poisoning, defined as a non-fatal act in which an individual deliberately ingests a substance in excess of any prescribed or generally recognised therapeutic dosage (Kreitman, 1977). The extent of suicidal intent, if any, was not considered when the 'diagnosis' was made. For the purposes of the present analysis only the 50 economically active males from the original sample were considered. Twenty-five were unemployed and 25 employed at the time of admission.

Subjects were given a structured interview in which data were collected on demographic, clinical, and treatment variables. This paper focuses on results obtained using three instruments which operationalise the key concepts of hopelessness, depression, and suicidal intent. Hopelessness was described by Beck in terms of a system of cognitive schemata that share the common element of negative expectations regarding the world, the self, and the future. The Hopelessness Scale (HS) (Beck *et al*, 1974*a*) is a self-rating scale consisting of 20 statements of thoughts or feelings about the future which the subject rates true or false. For every statement (of which 9 were keyed false and 11 keyed true) each response was assigned a score of 0 or 1, and the total hopelessness score (maximum = 20) was the sum of scores on individual items. Degree of depression was assessed by the Beck Depression Inventory (BDI) (Beck, 1970), a self-report instrument which measures depression as a syndrome rather than as a mood or diagnosis. The total score (maximum = 63) reflects both the number and severity of 21 possible symptoms or items (each rated on a scale of 0–3). Both the HS and the BDI were modified by rewriting items in the past tense and adding the word 'recently' in order to help subjects recapture their feelings prior to the parasuicidal act. Suicidal intent was conceptualised in terms of the relative weight of the patient's wish to live and wish to die, and the degree to which these suicidal wishes were transformed into a concrete act orientated towards death. The Suicidal Intent Scale (SIS) (Beck *et al*, 1974*b*) is a 15-item questionnaire, each item scoring 0–2 (therefore with a possible maximum of 30). The first part of the SIS ('Circumstances', consisting of 8 items) is concerned with the circumstances of the act; the second part ('Self-report', consisting of 7 items) assesses the subject's thoughts and feelings at the time of the act.

All data analyses reported in this paper were obtained using the Statistical Package for the Social Sciences (SPSS) (Nie *et al*, 1975). The statistical significance of differences between employed and unemployed groups was assessed by means of the χ^2 test using Yates' correction, where appropriate (categorical data), or the t-test (continuous data). Covariance analyses were performed in order to assess the main effect of employment status on hopelessness, controlling for the effect of depression, and on depression after partialling out the effect of hopelessness. The association between the major variables was represented throughout by the Pearson product-moment correlation coefficient. Partial correlation coefficients were also calculated in order to describe the relationship between two variables (e.g. suicidal intent and hopelessness) while adjusting for the effects of a third (e.g. depression). All P values are two-tailed, and the significance level (α) was set at 0.05 throughout.

Results

Compared with the rest of the economically active male parasuicides admitted to the RPTC during the same year, the study subsample ($n=50$) did not differ significantly in mean age, proportion reporting a previous hospitalised parasuicide, marital status, or social class breakdown.

Within the study sample, a comparison of the employed and unemployed groups on a number of selected demographic and clinical variables revealed two significant findings. More of the employed ($n=9$) than unemployed ($n=2$) were diagnosed depressed (χ^2 (depressed versus rest) = 4.25, d.f. = 1, $P<0.05$), even though the numbers diagnosed psychiatrically ill (10 employed, 6 unemployed) did not differ significantly. In respect of personality diagnosis, significantly more of the unemployed ($n=14$) than employed ($n=4$) were rated abnormal (χ^2 (normal versus rest) = 5.58, d.f. = 1, $P<0.02$). The groups did not differ in respect of marital status (the majority were unmarried), social class (the majority were in manual occupations), mean age (36 years among the unemployed, 33 years among the employed), current psychiatric status (the majority were receiving no treatment), or psychiatric disposal (half the sample were receiving in-patient, out-patient or general practitioner after-care). The tendency for more of the unemployed ($n=14$) than employed ($n=8$) to report a previous hospitalised parasuicide did not reach statistical significance.

The mean score for all 50 men was 4.0 (s.d. = 3.0) on the Circumstances part of the SIS and 6.2 (s.d. = 3.7) on the Self-Report part. The overall mean of 10.2 (s.d. = 5.6) was close to the typical value obtained from similar samples of parasuicides. The mean BDI score for the subsample was 25.4 (s.d. = 10.8), corresponding to a clinical judgement of moderate severity in two earlier studies (Beck *et al*, 1961; Metcalfe & Goldman, 1965). The mean HS score was 11.7 (s.d. = 5.1), higher than that reported in five previous studies (Pokorny *et al*, 1975; Minkoff *et al*, 1973; Beck *et al*, 1975; Goldney, 1981; Wetzel *et al*, 1980).

Comparisons between employed and unemployed revealed no differences in relation to part or total SIS scores. On the other hand, the unemployed scored significantly higher (i.e. worse) on both the BDI and the HS (Table I). The association between employment status on the one hand and depression and hopelessness on the other was explored further in two analyses of covariance (Table I). After controlling for HS score, employment status was no longer significant ($P>0.04$) in explaining variation in the

2. d.f.$=48$ (where $n=50$) or 23 (where $n=25$).
3. d.f.$=47$ (where $n=50$) or 22 (where $n=25$).

BDI score. However, the main effect for employment status remained highly significant ($P=0.008$) in accounting for variation in the HS score after partialling out the effect of the BDI score. Thus, the original finding of a significantly greater level of hopelessness in the unemployed group is confirmed, even after taking account of the higher BDI score among the unemployed; whereas the finding of a significantly greater degree of depression among the unemployed has been shown to be misleading, in that it reflects the higher level of hopelessness in this group; hopelessness, rather than depression, seems to be the important discriminator.

Scores on the BDI and the HS were highly correlated over the whole sample ($r=0.60$, $P<0.001$), and among employed and unemployed separately ($r=0.51$, $P=0.01$, in each group). The correlations between these scores and the SIS score, for the whole sample and for each group, are shown in Table II. Level of suicidal intent is significantly associated with both hopelessness and depression in the whole sample. However, somewhat different patterns of relationships are observed among the unemployed and employed groups: in the unemployed group depression is significantly correlated with suicidal intent, whereas hopelessness is not; among the employed, hopelessness is significantly associated with suicidal intent, but depression is not. However, formal statistical tests of the differences between correlations shown in each column of Table II (unemployed versus employed) shows that the only significant finding relates to the correlation between suicidal intent and hopelessness, controlling for depression ($r=0$ among the unemployed, $r=0.59$ among the employed; $z=2.2$, $P<0.05$).

Discussion

Before discussing the major findings of this study, attention should be drawn to a number of factors which may limit their generalisation. Firstly, results are reported for men only; clinical correlates of unemployment among female parasuicides may or may not be similar. Secondly, the rating of unemployment is limited inasmuch as no information was recorded on the duration of the unemployment spell, but evidence from Edinburgh (Platt & Kreitman, 1985) and Oxford (Hawton & Rose, 1986) in 1982 and from elsewhere in the 1960s (Smith & Davidson, 1971; Morgan *et al*, 1975) suggests that it is probably reasonable to assume that the majority of unemployed parasuicides in the present study had gone at least six months without a job. The final shortcoming of the study is the small number of subjects in the sample. However, it has been shown that the sample is broadly representative of all economically active male parasuicide patients admitted to the Centre during the year of study. The findings are thus probably generalisable to this larger population, which is itself fairly representative of all medically-treated parasuicides (Kennedy & Kreitman, 1973).

The first set of data which require comment are the comparisons on the key clinical variables of suicidal intent, hopelessness, and depression. The failure to differentiate between groups on the SIS is unlikely to have been caused by any social desirability effect, since employed and unemployed were rated similarly on the objective Circumstances part as well as the more subjective Self-Report section. Had the sample recorded high levels of suicidal intent, then any employment status effect might have been masked or attenuated by a more powerful underlying psychopathology. However, the majority of both groups were not given a psychiatric diagnosis and SIS scores tended to be moderate.

The results relating to depression and hopelessness were in the expected direction, with higher scores (i.e. worse outcome) among the unemployed. Covariance analysis supports the robustness of the finding relating to HS score, but casts doubt on the independent status of the BDI result. The HS score is higher among the unemployed *despite* the fact that the BDI score is also higher, whereas the BDI score is higher in the unemployed group *because* hopelessness is more pronounced. The inconsistency between the BDI and clinical diagnosis results – whereas the unemployed were rated more depressed overall, there were more patients in the employed group given a diagnosis of depression – may be more appearent than real. The BDI is not intended to produce a clinical diagnosis, but rather to measure the behavioural manifestations of depression. There may be more depressive symptomatology overall among the unemployed, while a greater proportion of the employed are psychiatrically ill (i.e. clinically depressed). Nevertheless, we are mindful of Buglass's comments on the finding of a relationship between diagnosed depression and social class in a sample of parasuicides: the higher the social class, the more frequent the diagnosis of depression (Buglass, 1976). She argued that while this may reflect something about the patients' mental state, it may equally be that the clinical assessment patients receive is influenced by their social status. She referred to a study of medical in-patients by Schwab *et al* (1967), in which doctors appeared to show a marked bias towards a diagnosis of depression in upper-class patients which was at variance with test results using the BDI. We cannot dismiss the possibility that the patient's employment status may also influence doctors' clinical judgement.

The matrix of relationships between depression, hopelessness and suicidal intent was somewhat dissimilar between the two groups (Table II). Overall, the results mirrored those of the main study from which this sample was taken and of previous (mostly American) studies (Dyer & Kreitman, 1984). Among employed parasuicides the strength of the association between suicidal intent and hopelessness was particularly marked, while the correlation between suicidal intent and depression was not statistically significant. Among the unemployed, however, there was a significant association between suicidal intent and depression (which remained of borderline significance even after controlling for hopelessness) and no relationship at all between suicidal intent and hopelessness. This finding has only been reported in one previous study (Pokorny *et al*, 1975). Taken at face value, it casts doubt on the unequivocal assertion of Beck *et al* (1975) that "hopelessness accounts for the relationship between depression and suicidal intent... (It) is a stronger indication of suicidal intent than is depression itself". However, there is a risk of over-interpreting the importance of these differences. The number of subjects was small, and only one correlation (between suicidal intent and hopelessness, controlling for depression) was significantly greater in one group than in the other. Although further discussion would best be postponed until the findings have been replicated in a larger sample, extremely high levels of hopelessness may increase the risk of self-harmful behaviour without any discernible impact on the degree of suicidal intent.

The correlational analysis may raise questions about the relationship between the major clinical variables in the study. However, it does not undermine the outstanding finding of a significant relationship between hopelessness and unemployment. Hopelessness may be a key social-psychological variable for inclusion in any model of the pathways which lead from unemployment to parasuicide (or suicidal behaviour generally). Fifty years ago, clinicians drew attention to the impact of unemployment on attitudes to the future (e.g. Rundquist & Sletto, 1936; Israeli, 1935; for a more extensive review, see Eisenberg & Lazarsfeld, 1938). Jahoda *et al* (1933) differentiated the unemployed of Marienthal into four groups according to their prevailing attitudes. Apart from the 'unbroken', the remaining groups, while differing in some respects, shared at least one common feature – that of hopelessness.

Surprisingly, little attention has been paid to the prevalence or extent of hopelessness among the unemployed in the numerous more recent publications which utilise standardised psychometric tests to measure psychological well-being. Some tangential data are provided by Feather (1982), who showed that unemployed males tend to be more apathetic and lacking in interest than those in employment. Payne *et al* (1984) examined health, well-being, perceptions, and beliefs among middle-class and working-class white married men aged 25–39 who had been unemployed for 6–11 months. A high proportion reported anxiety about what would happen to them in the future, e.g. whether they would become permanently unemployable, lose their self-respect, become really depressed, lose the ability to make decisions, or have insoluble money problems. The working-class sample were significantly more fatalistic, exhibiting a higher degree of belief in external control. Warr (1984) proposes that insecurity about the future is one of the major features of the unemployed person's role which may account for the reduction in psychological well-being which he or she suffers. We believe that more attention should be paid to the assessment of hopelessness in employed and unemployed samples, and to an elucidation of its significance in the genesis of parasuicidal behaviour, particularly among the unemployed.

Acknowledgements

We are grateful to Dr A. T. Proudfoot, Dr L. F. Prescott, and Professor I. Oswald for allowing us to interview patients in the Regional Poisoning Treatment Centre, and to other staff of the Centre for their co-operation. Dr N. Kreitman read earlier drafts of the paper and made several helpful suggestions and criticisms.

Psychiatric Morbidity in Primary Health Care

A Two-stage Screening Procedure in Developing Countries: Choice of Instruments and Cost-effectiveness

B. SEN, G. WILKINSON and J. J. MARI

The use in two developing countries of a two-stage psychiatric screening procedure with an emphasis on minor morbidity is described. This was the first use of the Self-Reporting Questionnaire and Clinical Interview Schedule in conjunction. Health auxiliaries with limited training administered the first-stage screening instrument. In comparison with other psychiatric screening techniques used in developing countries, the procedure described may prove to be more cost-effective in primary care and community surveys, and more appropriate for assessing the wide range of minor psychiatric morbidity commonly encountered in such settings.

A series of psychiatric field surveys have been reported from the developing world since the 1960s, but such surveys, especially if carried out by teams of psychiatrists, use resources (in money, time and trained manpower), which developing countries can ill afford. Regrettably, the majority of these studies have utilised screening questionnaires that have not been adequately validated, and unstandardised clinical interviews for psychiatric assessment. An exception is that by Kapur (1975), in which the development and application of a multi-stage standardised screening questionnaire was reported in some detail.

This paper described the use of a two-stage screening procedure suitable for application in primary health care facilities and community surveys in developing countries. Two major issues will be discussed: the choice of instruments, and the cost-effectiveness of the procedure. This is illustrated with reference to two studies which were carried out in the cities of Calcutta in India and Sao Paulo in Brazil (Mari & Williams, 1986a).

Method

Study areas

Two-stage psychiatric screening was conducted in three primary care clinics in each city. The majority of patients were skilled, semi-skilled, or unskilled manual workers and hawkers, living mostly in slums or crowded housing with primitive sanitary conditions. More than half of the population in both areas were either illiterate or had not completed elementary schooling.

Research instruments

Self-reporting questionnaire (SRQ) (Harding *et al*, 1980). This consists of 25 items, and is divided into two sections: the first 20 items are designed to detect non-psychotic disorders, and the remainder to screen for psychotic disorders and epilepsy. A version consisting of the first 20 items was used for both the studies reported here; it usually takes 5–15 minutes to administer. For the Calcutta study, translation of the questionnaire from English into Bengali was carried out by the research psychiatrist (BS) and back-translated by a school teacher unacquainted with the original English version. The back-translation was subsequently compared with the original by BS and an English psychiatrist, to obtain semantic equivalence of the items. Minor discrepancies which had occurred necessitated slight modifications. A Portugese translation prepared for a WHO study (Harding *et al*, 1983a) was used in Sao Paulo.

Clinical Interview Schedule (CIS) (Goldberg *et al*, 1970). This is a standardised, semi-structured inventory designed for use in community surveys and general practice (Shepherd & Clare, 1981). Its feasibility in general practice and primary care settings has been tested in settings as varied as the UK (Goldberg & Blackwell, 1970), Brazil (Mari & Williams, 1984), Jamaica (Harding, 1976), Kenya (Dhadphale *et al*, 1983), Mexico (Medina-Mora *et al*, 1983) and Taiwan (Cheng, 1985). Its reliability has also been tested in a number of countries (Goldberg *et al*, 1970; Campillo-Serrano *et al*, 1981, Cheng *et al*, 1982, Mari *et al*, 1986). All operational terms in the CIS are carefully defined, and detailed criteria for rating provided in a manual. It is intended for administration by a psychiatrist standardised in its use. The CIS was translated into Bengali and Portugese in the manner described above. The interview takes 10–15 minutes for a healthy individual and 30–50 minutes for patients with psychiatric symptoms.

Collection of data

The Calcutta study was designed as a pilot project to validate the SRQ and establish its best cut-off point. The Sao Paulo study was part of a larger research project, for which a feasibility study had previously been conducted (Mari & Williams, 1984).

The Calcutta study was conducted during July and August, 1985, while the Sao Paulo one took six months (September 1982 to February 1983). Consecutive adult patients (aged 15 years and above in Calcutta, 16 years and above in Sao Paulo) attending the primary care clinics were screened with the SRQ (In Sao Paulo the General Health Questionnaire, GHQ-12, (Goldberg, 1978) was simultaneously administered). A random sample of 'probable cases' and approximately the same number of 'probable non-cases' were then interviewed using the CIS. The initial cut-off point for a 'probable case' for this purpose was decided on the basis of GHQ-12 scores in Sao Paulo (Mari & Williams, 1986a); in Calcutta it was taken as the median of the SRQ cut-off scores (7–8) determined by Harding *et al* (1980) and by Mari & Williams (1986a). The psychiatric interview was conducted 'blind', i.e. without knowledge of the patient's SRQ status. Patients who were too ill to answer the questionnaires (two in Calcutta; eight in Sao Paulo), and those who had already attended once during the exercise were excluded from the study. The psychiatric interview was refused by three respondents in Sao Paulo, but by none in Calcutta.

Basic sociodemographic data (age, sex, marital status, education, occupation and family income) were collected for each patient screened. The screening procedure was carried out independently of the usual consultation process, but any incovenience to the patients, e.g. having to wait too long for the psychiatric interview, was minimised. In general, patients selected for the psychiatric interview seemed happy to have two doctors for consultation instead of the usual one (the physician at the primary care clinic). The enthusiastic cooperation of both the clinic staff and the patients contributed considerably towards the successful completion of the projects.

Personnel and training

In Calcutta, three health workers, who each had 8–12 years of schooling followed by training in primary health care, carried out the first-stage screening. They received a 30-minute orientation session, during which it was ascertained that they understood the SRQ questions and the procedure required of them. In Sao Paulo, screening with the SRQ was conducted by a qualified and experienced social worker, who had had four years of university training; she received one week's training in administration of the SRQ.

Results

In Calcutta, a total of 202 patients were screened with the SRQ, of whom 114 (56%) were interviewed by the research psychiatrist. In Sao Paulo, 875 patients were screened and 260 (30%) were interviewed. There were no significant differences in either area in sociodemographic variables between the total sample and the subsample selected for interview. Thus, the subsample may be regarded as representative of the adult patients attending the primary care clinics in the respective cities.

Appendix 1 provides a summary definition of the statistics used to determine the validity of the SRQ as a screening instrument. Sensitivity (i.e. the proportion of cases correctly identified by the screening test) is said to indicate the 'utility' (the extent of benefit) of a test, whereas the proportion of false negatives and false positives, which together represent the overall misclassification rate (at a given prevalence), are representative of the 'cost' of a test. The 'cost' constitutes the cost of referral of the false positives (for the individual and for the physician) (Skuse & Williams, 1984). The missed cases or false negatives also represent a 'cost' for the subjects concerned, and may be estimated in terms of work lost due to lack of treatment.

The positive and negative predictive values are more useful in determining the 'utility' of a questionnaire for screening purposes. They measure the extent to which the test succeeds in *predicting* psychiatric cases or non-cases

TABLE I
Cross-tabulation of observed and scaled-up SRQ and CIS results

SRQ finding	*CIS finding*		*Total sample*	*Expected CIS finding for total sample*[1]	
	Positive	*Negative*		*Positive*	*Negative*
Calcutta					
Positive	38	12	105	80 (*A*)	25 (*B*)
Negative	14	50	97	21 (*C*)	76 (*D*)
Sao Paulo					
Positive	114	26	455	371 (*A*)	84 (*B*)
Negative	22	98	420	77 (*C*)	343 (*D*)

1. A–D are defined in Appendix 1.

TABLE II
Validation indices for the SRQ obtained in Calcutta and Sao Paulo (percentages)

Index	*Calcutta*	*Sao Paulo*
Sensitivity	79	83
Specificity	75	80
Positive predictive value	76	82
Negative predictive value	78	82
Misclassification rate	23	18

among the primary care clinic patients or community. The predictive values vary with the prevalence of psychiatric morbidity; the higher the prevalence the greater the positive predictive value (Meehl & Rosen, 1955; Galen & Gambino, 1975).

Table I gives the results found in Calcutta and Sao Paulo respectively, and Table II gives the validation indices derived on the principles described in Appendix 1. The optimum cut-off point of the SRQ in Calcutta was 11–12, while in Sao Paulo it was 7–8. The cut-off point was determined by calculating the sensitivities and specificities for a range of values of the case/non-case threshold; the chosen threshold was that which permitted the best trade-off between sensitivity and specificity, which are inversely related.

All indices of validity were somewhat higher in the Sao Paulo study, although the differences were not statistically significant.

Discussion

The studies described here are the first to use the SRQ in conjunction with the CIS. The objective of this paper is to illustrate a two-stage screening procedure which may be cost-effective, and which could be applied in large-scale primary care or community surveys with the emphasis on minor psychiatric morbidity in developing countries, where resources are always scarce.

These two investigations have concentrated on two aspects. Firstly, the feasibility of using health auxilliaries (e.g. social workers and health workers trained in primary health care) with limited training to screen effectively for psychiatric disorders was studied. Although health auxilliaries were used for first-stage psychiatric screening in the World Health Organisation (WHO) collaborative study (Harding *et al*, 1983a,b), their work has not yet been replicated. The Calcutta study also served as an initial assessment of the extent to which the SRQ could be successfully used as a screening tool by auxilliaries with limited education and minimal training in the administration of the questionnaire. Secondly, the success of the procedure in screening for the wide range of psychiatric disturbances which are commonly seen in primary care or in the community was examined. Adequate validation of the first-stage screening instrument and choice of the appropriate instrument for second-stage screening are crucial for both these purposes.

Choice and validation of the SRQ

The choice of the SRQ was influenced mainly by the fact that this instrument was developed by the WHO for use in primary care settings in developing countries (including India and Brazil), where it has previously been validated (Harding *et al*, 1983b). It was also determined on an earlier occasion (Sen, unpublished) in Calcutta that health auxilliaries with limited education found the SRQ, with its yes/no responses, less complicated to administer than the GHQ (Goldberg & Blackwell, 1970), with which they experienced problems in conveying to the respondents the concepts of "no more than usual" and "more than usual". This problem was experienced in Sao Paulo to the extent that respondents did not understand some of the questions on the GHQ-30 (Mari & Williams, 1984). This difficulty did not, however, recur with the GHQ-12 on a subsequent occasion (Mari & Williams, 1985), although it was observed that administration of the GHQ-12 took more time than the SRQ. In addition, the social worker administering the two questionnaires reported that the SRQ questions were more acceptable to the respondents than the GHQ-12.

Harding *et al* (1983a), in their WHO study in seven developing countries, stated that there is considerable variation in the optimal cut-off point (varying between 5–6 and 10–11 in different areas) which "results from substantial variation in response rates". The most likely explanation for this difference in the two studies described here (11–12 in Calcutta and 7–8 in Sao Paulo) may lie in the varying socio-cultural characteristics of the populations studied; e.g. in Sao Paulo, a lower cut-off point (5–6) in men gave the best results (Mari & Williams, 1985). There is also evidence that individuals with little or no education are more likely to be false positive on the SRQ (and the GHQ) than those who had more than eight years of schooling (Mari & Williams, 1986b). The fact that 47% of the respondents in Calcutta, but only 24% of the respondents in Sao Paulo, had less than one year of schooling tends to favour the use of a higher cut-off point for the SRQ in Calcutta.

There is some evidence that increasing psychiatric experience of the rater is associated with a tendency to rate less abnormality (Copeland *et al*, 1975); Wing *et al* (1977) also reached similar conclusions. This might mean that the less the interviewer's exposure to psychiatric disturbances, the more is his likelihood of rating a greater number of symptoms. There is some suggestion that similar factors operated in the Calcutta study, when compared with that in Sao Paulo. In Calcutta, the three health workers who administered the SRQ had had little mental health experience and only a brief orientation session in conducting the SRQ screening. In Sao Paulo, on the other hand, the SRQ was administered by a qualified social worker with some training in mental health and, in addition, a week's training in the administration of the SRQ. Although the SRQ simply requires yes/no answers, an element of judgement is involved in determining the presence or absence of a symptom with answers like: "Yes – once in a while – it doesn't upset me greatly" or "Yes, some time back".

The two studies discussed here support the recommendation (Harding *et al*, 1983a) that the SRQ should be adequately validated – for determination of the cut-off point – before being employed for large-scale primary care or community surveys.

Appropriateness of the CIS for second-stage screening

Dohrenwend & Dohrenwend (1982), in their global review of epidemiological literature in psychiatry, commented on "the central unsolved problem of case identification" among the studies published up to the 1970s. In the majority of these studies, unstandardised psychiatric interviews by psychiatrists remained the ultimate criterion to determine 'caseness', with the result that the reported prevalence rates varied so widely that it rendered any comparison between them virtually meaningless. This applies especially to the non-psychotic disorders, which constitute the overwhelming majority of psychiatric disturbances in primary care or in community samples.

Many studies, both in India and elsewhere, have applied the operational definition of a case adopted by the WHO Expert Committee on Mental Health (1960). But, as Wig (1982) points out, this definition concentrates solely on the severe types of mental illness, excluding 'minor' psychiatric disorders.

It is now generally agreed that the two-stage screening procedure, which utilises a validated screening technique followed by a standardised psychiatric interview, is an improvement on earlier studies in estimating the prevalence of psychiatric disorders in primary care or in the general population. The WHO Collaborative Study on Strategies for Extending Mental Health Care (Harding *et al*, 1983a) utilised the SRQ for first-stage screening and the Present State Examination (PSE) (Wing *et al*, 1974) for subsequent psychiatric interview.

However, the PSE was developed in a hospital setting and rates symptoms that must be "clinically fairly severe"; it only identifies those psychiatric disorders "familiar to psychiatrists in hospital practice" (Wing *et al.* 1981). There is also a suggestion that the PSE, when used as a standardised instrument for second-stage screening with the GHQ or SRQ for the first stage, produces low validation indices (Cleary *et al*, 1982; Harding *et al*, 1983b; Byrne, 1984).

Although the focus of psychiatric epidemiology has shifted from hospital studies to primary care and community surveys, case definition criteria have lagged behind, remaining rooted in concepts derived from hospitalised patients. As Williams *et al* (1980) point out, "it is as if, in a study of the community prevalence of diabetes, diabetes were defined by the presence of diabetic retinopathy".

In the two studies illustrated here, the CIS was considered to be the most appropriate instrument for psychiatric assessment for two reasons. It was developed so that it "should be acceptable to individuals who may not see themselves as psychiatrically disturbed", and "the content of the interview should be appropriate to the types of psychiatric disturbance encountered in the community" (Goldberg *et al*, 1970).

Cost-effectiveness of the procedure

For the purposes of this paper, cost-effectiveness is assumed to be concerned with the 'least cost' solution to a given objective, which in this instance is the estimation of psychiatric morbidity in primary health care and the community in developing countries. As Kapur (1975) has shown, to have the first-stage psychiatric screening conducted by health auxilliaries not only saves on the research psychiatrist's time, but utilises health personnel available in most developing countries at comparatively low cost, and thus contributes greatly to the cost-effectiveness of the project. This applies to the two studies described here. Moreover, in the Calcutta study the health auxilliaries were able to conduct the first-stage screening as part of their routine duties.

Assuming that two or more screening procedures are equally cost-effective at a given level of prevalence, a further reduction in the proportion of false positives and false negatives obtained by one or other of the procedures should result in an increase in the cost-effectiveness of that procedure. In both Calcutta and

Sao Paulo, around one-fifth of the screened individuals were estimated to be misclassified, which does not compare unfavourably with the proportions misclassified with the GHQ-30 (Vieweg & Hedlund, 1983) or the GHQ-12 (Mari & Williams, 1985). It is likely that a period of training of health auxilliaries might lead to a lowering of the misclassification rate, and thus make the test more cost-effective. For a technical discussion of misclassification as an indicator of cost-effectiveness, the reader is referred to Skuse & Williams (1984).

The procedure discussed here will form the basis of community surveys now being planned to be conducted in both Calcutta and Sao Paulo. Replication of this procedure in other developing countries may lead not only to the simplification of the screening questionnaire (e.g. by reducing the number of questions), but also to more information about minor psychiatric morbidity, which has been inadequately investigated in developing countries. It is hoped that this will lead to early intervention in their management, possibly by health auxilliaries trained in mental health care (Wig *et al*, 1981), and thus prove to be of value in preventing patients with primary psychological problems being subjected to unnecessary and often expensive medical investigation (Mitchell, 1985). There seems to be little doubt, however, that such research endeavours will, at the very least, serve to focus attention on the extent of minor psychiatric morbidity in the health centres – where, despite causing considerable distress, they go largely unrecognised.

Appendix 1

A summary definition of the statistical norms used in the analysis of SRQ as a screening instrument is given here. The quantities *A* to *D* are defined in Table III.

TABLE III
Quantities involved in definition of statistical norms

SRQ finding	*Psychiatric assessment (using CIS)* *Positive*	*Negative*
Positive	*A*	*B* (false positive)
Negative	*C* (false negative)	*D*

$$\textit{Sensitivity}\ (\%) = \frac{\text{Number of cases correctly identified by SRQ}}{\text{Actual number of cases}}$$

$$= \frac{A}{A+C} \times 100$$

$$\textit{Specificity}\ (\%) = \frac{\text{Number of non-cases correctly identified by SRQ}}{\text{Actual number of non-cases}}$$

$$= \frac{D}{B+D} \times 100$$

Percentage of false positives = 100 – specificity

Percentage of false negatives = 100 – sensitivity

$$\textit{Misclassification rate} = \frac{\text{False positives} + \text{False negatives}}{\text{Grand total}}$$

$$= \frac{B+C}{A+B+C+D}$$

Positive predictive value (PPV) (probability of a probable case being an actual case)

$$= \frac{\text{Number of cases correctly identified by SRQ}}{\text{Number of probable cases}} = \frac{A}{A+B}$$

Negative predictive value (NPV)(probability of a probable non-case being an actual non-case)

$$= \frac{\text{Number of non-cases correctly identified by SRQ}}{\text{Number of probable non-cases}} = \frac{D}{C+D}$$

Family-Genetic Studies and Identification of Valid Diagnostic Categories in Adult and Child Psychiatry

JAMES F. LECKMAN, MYRNA M. WEISSMAN, DAVID L. PAULS and KENNETH K. KIDD

Family-genetic studies of child and adult psychiatric disorders have become increasingly fashionable over the past decade. The development of structured diagnostic interview schedules, the emergence of uniform diagnostic criteria such as DSM–III, and the use of refined design and analytic techniques from the field of chronic disease epidemiology have made substantial contributions to the methodology of such studies. Advances in molecular genetics, particularly our emerging capacity to perform chromosomal linkage studies throughout the human genome, have renewed hope that the constitutional underpinnings of some psychiatric disorders can be identified and that the pathophysiology of these disorders can be elucidated. Family-genetic techniques in child and adult psychiatry are discussed with a particular focus on their potential value in validating diagnostic categories spanning developmental epochs.

A variety of 'family-genetic' strategies have been developed over the past century (Kidd & Matthysee, 1978). Classically, four types of evidence are suggestive of genetic or familial factors being aetiologically important in behavioural disorders: (a) an increased frequency of the disorder observed in at-risk family members; (b) an increased frequency of the disorder in the adopted-away biological offspring of affected individuals; (c) a higher concordance for the disorder among monozygotic than among dizygotic twins; and (d) evidence for a specific genetic factor transmitted in an area adjacent to a known chromosomal locus. Although this paper will focus primarily on the first and last of these, many of the comments regarding assessment methodologies apply equally to twin and adoption studies.

Recent methodological advances

Each of these family-genetic strategies requires the ability to assess reliably the psychiatric status of large numbers of individuals, many of whom have never been in treatment. Over the past decade, family-genetic studies in the USA have increasingly been influenced by putative advances in psychiatric nosology and by corresponding changes in assessment procedures. Historically, the search for reliable diagnostic criteria and the development of standardised methods to elicit the needed information can be traced to work at Washington University in St Louis. Feighner *et al* (1972) published criteria for 15 major psychiatric disorders and developed a structured interview instrument, the Renard Diagnostic Interview, to collect systematically information relevant to the application of these criteria (Robins *et al*, 1977). These criteria were subsequently modified and elaborated, and specific 'Research Diagnostic Criteria' (RDC) were proposed (Spitzer *et al*, 1978*a*; Endicott & Spitzer, 1979). The RDC focused on past and present episodes of illness and provided inclusion and exclusion criteria by which clinically homogeneous groups of patients may be diagnosed and studied. The Schedule for Affective Disorders and Schizophrenia (SADS), a structured interview, was developed at the same time to ensure that the information on signs and symptoms were collected systematically (Spitzer & Endicott, 1978). A 'lifetime' version of the SADS was also developed to record information concerning past as well as present episodes of illness for use in family studies. Use of the RDC and the SADS greatly improved inter-rater agreement (Endicott & Spitzer, 1979). DSM–III (American Psychiatric Association, 1980) is a direct descendant of these earlier diagnostic schemata.

Similar developments in the standardisation of diagnoses have taken place in the United Kingdom – particularly the work of Wing *et al* (1967, 1974) on the Present State Examination (PSE), which incorporates standard methods of defining, eliciting, and recording information about 140 symptoms and signs in an interview format. The PSE is reliable, and modified versions have been widely used in large-scale international studies (Wing *et al*, 1977). Only recently, however, have attempts been made to modify the PSE to include information on 'lifetime' symptoms (Torgersen, 1983).

The movement to define reliable categories has also led in the USA to a proliferation of diagnostic categories in both the adult and childhood areas of DSM–III. Whether this is a real advance or merely legerdemain is debatable (Rutter & Shaffer, 1980; Tyrer, 1985); our ability to construct reliable diagnostic categories may have outstripped our ability to validate such categories. The hierarchical organisation of diagnoses in DSM–III has also proved to be problematic. Although the exclusion of some diagnoses, such as anxiety disorders, during episodes of depression or schizophrenia is parsimonious, it may be misleading when the validity of the hierarchical scheme is unproven (Leckman *et al*, 1983*a*). The revision of DSM–III currently under way largely does away with these exclusionary criteria.

Validation of diagnostic categories and distinctions

How can we 'validate' a diagnostic category? In the absence of specific neuropathological evidence, how can we establish that any two individuals are suffering or have suffered from the same disorder? This fundamental question has yet to be answered for most, if not all, psychiatric disorders. The identification of clinically homogenous groups of patients is insufficient (Rutter & Shaffer, 1980). DSM–III offers many examples of such *a priori* groupings. While they may be acceptable first approximations, they incautiously assume that cross-sectional clinical homogeneity accurately reflects an underlying aetiological homogeneity. Indeed, some medical disorders with similar pathophysiological and clinical expressions, have been found to be aetiologically heterogenous, e.g. anemias, coagulation disorders, and congenital deafness. Historically, most psychiatric researchers have emphasised the use and importance of natural history data regarding the onset, course, and outcome to establish valid diagnostic categories. Differential response to treatment and the presence of a 'biological-marker' have more recently been proposed as alternate means to validate categories of psychiatric disease. Although a thorough review of these strategies is beyond the scope of this paper, it is clear that none of them is wholly adequate. Each is vulnerable to the presence of factors which are unrelated to the underlying disease process but which may dramatically influence its onset, course, or treatment outcome.

The use of family history and family study data to help define nosological categories more precisely is well-known (Robins & Guze, 1970; Spitzer *et al*, 1978*b*). For example, more than a score of family studies of schizophrenic probands have found that the risk of schizophrenia and related conditions significantly exceeds the risk observed in the general population, thus confirming Kraepelin's (1904) original view that familial factors are aetiologically important in this disorder. Although the familial nature of schizophrenia has recently been challenged, the most rigorous family studies of schizophrenia using DSM–III criteria and structured interviews continue to provide strong support for the view that schizophrenia is a familial disorder (Tsuang *et al*, 1980; Kendler *et al*, 1985). The Iowa studies have also helped to clarify the possible connections between schizophrenia and a variety of other disorders. While the relationship between schizophrenia, psychotic major depression, and schizoaffective disorders remain obscure, the evidence is persuasive that alcoholism, unipolar depression, non-psychotic depression, major depression, and some anxiety disorders are aetiologically unrelated to schizophrenia (Tsuang *et al*, 1980; Kendler *et al*, 1985).

In providing an independent source of data, family-genetic studies also allow investigators to assess directly the importance of various clinical features of a putative disorder. By stratifying groups of at-risk relatives on the basis of the presence or absence of a particular symptom or pattern of symptoms in the index cases, it has been possible to assess the predictive value of such symptoms or symptom constellations by their effect on the rates of illness and the types of illness among the relatives. Recent examples of such work have focused on the importance of primary social role impairment (Gershon *et al*, 1986), age of onset (Weissman *et al*, 1984*d*), sex of proband (Merikangas *et al*, 1985*a*), and 'endogenous' symptom patterns in discriminating familial from non-familial forms of major affective disorder (Leckman *et al*, 1984*a*,*b*; Andreasen *et al*, 1986).

Family study data have provided valuable information by tentatively identifying alternate manifestations of the same underlying diathesis. The relationship of obsessive-compulsive disorder to Gilles de la Tourette's syndrome (TS) is one such example, where high rates of obsessive-compulsive disorder were found among the first-degree relatives of probands with TS (Pauls *et al*, 1986*b*; Pauls & Leckman, 1986). Better known is the apparent association of schizophrenia with a 'spectrum' of related disorders (Kety *et al*, 1968; Kendler & Gruenberg, 1984).

Restratification techniques have also proved useful in studying the relationship of co-morbid conditions, such as panic disorder and alcoholism, with major affective disorder (Leckman *et al*, 1983*b*; Merikangas *et al*, 1985*b*). In the case of panic disorder, we have investigated the relationship between symptoms of depression and recurrent panic attacks as part of a large scale family-genetic study of major affective disorders (Weissman *et al*, 1984*a*,*b*). As noted above, the prevailing diagnostic conventions in the United States assert that prominent anxiety symptoms (including recurrent panic attacks) that occur solely during depressive episodes do not have any nosological significance. Our family study data, on the contrary, have indicated that the association of depression and recurrent panic attacks in index cases was associated with increased rates of depression and anxiety in the adult at-risk relatives, compared with the adult at-risk relatives of depressed probands without prominent anxiety symptoms (Leckman *et al*, 1983*a*,*b*). This increased risk was observed regardless of whether or not the recurrent panic attacks occurred concurrently with the depressive episodes. Similar findings were also observed in the offspring under the age of 18 years in these families (Weissman *et al*, 1984*c*).

These data call into question the validity of the prevailing diagnostic convention and suggest that additional studies are needed to clarify the aetiological relationship between recurrent panic attacks and depression; they have also led to the hypothesis that some forms of depression and some forms of 'panic disorder' partially or wholly share a common underlying diathesis. If this can be established and the critical clinical features identified, more precise studies in other areas of clinical investigation will follow. Specific differences in natural history, treatment response, and biological measures may be expected. Even our capacity to apply sophisticated mathematical models and to perform state-of-the-art genetic linkage studies in high-density families using newer recombinant DNA techniques will be enhanced through our ability to identify aetiologically more homogenous patient groups.

Another example of assessing the relationship of a co-morbid condition involves an effort to sort out the nosological significance of frequent symptoms of hyperactivity, attentional impairment, and impulsivity in children with TS. In a family study of TS we found that the at-risk relatives of probands with TS and attentional impairment had an increased rate of attentional impairment, but no increase in the rate of TS or chronic multiple tics compared with the at-risk relatives of probands with TS only (Pauls *et al*, 1986*a*). These data, together with the observation that the attentional impairment and the tics or TS did not co-segregate within these families, have led us to conclude that the TS diathesis is largely independent of the aetiological factors which underlie the attentional problems observed in a sizeable proportion of TS patients (over 50% in most clinic samples). The increased frequency of attentional problems among TS patients, which has been observed in clinic patients, may be due to a referral bias (Berkson's bias). Children with two disorders may be more likely to come to the attention of health care professionals, particularly if both adversely affect school performance and behaviour.

Limitations

The use of family study data to establish valid diagnostic criteria is largely limited to those disorders in which transmission within families is known to occur. As such, efforts to refine and validate criteria logically follow studies in which familial or genetic factors have been demonstrated to be aetiologically important. Even with this constraint, the list of disorders for which such a determination has been made is substantial and includes schizophrenic disorders, affective psychoses, paranoid states, some forms of alcoholism, panic disorder, agoraphobia, and anti-social personality disorder in adulthood; in children it includes infantile autism, attention deficit disorder, tic disorders, stuttering, and some learning disorders. In other instances, suitable studies have not yet been performed on which to judge the aetiological importance of familial or genetic factors. Conversely, hypotheses invoking environmental factors transmitted within families cannot be rejected for most psychiatric disorders. However, the potential importance of genetic factors in creating unique environments should not be discounted (Scarr & McCarthy, 1983).

On a more practical level, the need to establish 'lifetime' diagnostic estimates is associated with important methodological problems involved with the recall of symptoms for remote episodes of illness. These problems are compounded when the individual is dead or otherwise unavailable for direct interview. In such cases the diagnostic estimates must be made on the basis of indirect reports from other relatives or from medical records. The under-reporting of psychiatric disorders associated with indirect 'family history' methods has been well documented (Andreasen *et al*, 1977). Not surprisingly, individuals living in the closest proximity, such as spouses, are generally the best informants (Thompson *et al*, 1982). Nor is it surprising that severe disorders can be more consistently identified by family members (Orvaschel *et al*, 1982). These methodological difficulties culminate in making final 'best estimate' diagnoses on the basis of all available information. Inevitably, the quantity and quality of data available for this procedure are often quite variable. However, good inter-rater agreement using the best estimate method was found for major depression, depressive personality, alcoholism, drug abuse, panic disorder, phobia, and antisocial personality among interviewed individuals (Leckman *et al*, 1982).

The diagnostic procedures become even more problematic in dealing with childhood disorders. Although structured and semi-structured instruments have been developed for school-aged children (Herjanic *et al*, 1975; Puig-Antich & Chambers, 1978), the test-retest reliability of these instruments is marginal for many diagnoses (Chambers *et al*, 1985). Similarly, the level of parent-child agreement is often low. A related problem has to do with attempts to make childhood diagnoses, such as separation anxiety, retrospectively, in adult subjects who no longer display the symptoms. Many of these difficulties are substantive and may not yield to refinements in assessment methodology. Examination of these issues raises fundamental questions concerning the developmental continuities or discontinuities of psychopathological states. They also highlight the limitations in perception and recognition over time by individual children, parents, and investigators of mental disorders as opposed to states that are perceived as being within the range of 'normal' experience.

Another major limitation involves the potential effects of assortative mating – the tendency for couples with similar phenotypic traits to select one another more frequently than would be expected by chance alone. Assortative mating for psychiatric disorders in general, as well as for specific psychiatric disorders, has been consistently reported (Merikangas, 1982). This non-random mating can influence the distribution of disorders in a population, by increasing the population variance and the proportion of homozygous individuals, and so mislead the unwary investigator. The Danish Adoption Study and the American-Danish High Risk Project provide examples of the potentially confounding effects of this phenomenon in studies of schizophrenia (Rosenthal, 1975; Parnas, 1985).

Improvements in the statistical methods for handling these large data sets from family-genetic studies have included: the development of methods for quantifying lifetime prevalence which handle the age correction of the data without ancillary information on population age-specific incidence rates and are independent of mortality (Thompson & Weissman, 1981); the successful application of log-linear models to deal with potentially confounding variables which may be related to outcome (Kidd *et al*, 1981; Weissman *et al*, 1982); and the use of survival time models with non-proportional hazard functions (Weissman *et al*, 1984*d*; Wickramaratne *et al*, 1986).

Prospects for the future: genetic linkage studies

Genetic linkage has long been recognised as a way of demonstrating that a specific genetic factor is aetiologically important in the transmission of a particular disorder. If linkage can be demonstrated it may be possible, given the current revolution in human genetics, to isolate a specific genetic factor and gain insight into the basic constitutional events that may predispose an individual to the expression of a particular psychiatric disorder (Cloninger *et al*, 1983; Kidd, 1982, 1985). Equally exciting is the possibility that by ascertaining which individuals are at risk it will be possible through the use of appropriate longitudinal research designs to identify those risk and protective environmental factors which mediate the expression of the disorder. Important and rational strategies for treatment and possible prevention would also be anticipated.

Until a few years ago this method had limited applicability to human disorders, because of the small number of polymorphic genetic markers that were available. Over the past few years the field of human molecular genetics has changed dramatically. Using recombinant DNA techniques, investigators are identifying a growing number of highly polymorphic markers. As of mid-1985 over 800 new polymorphisms had been identified (Willard *et al*, 1985), and that number has significantly increased during the last two years. Since new polymorphisms are being discovered at an ever-increasing rate, it should be possible to construct a genetic linkage map of the entire human genome in the next few years. This development may have major consequences in the field of psychiatry. For example, the recent reports of Gerhard *et al* (1984) and Egeland *et al* (in press) detailing the possibility of linkage of manic-depressive disorder in large Amish pedigrees to markers on chromosome 11, if confirmed, may clarify the relationship of unipolar to bipolar affective disorders in at least some cases, as well as herald other dramatic advances in our understanding of this disorder.

Although the number of psychiatric disorders which may be amenable to this technique (i.e. for which a single major locus accounts for a sizeable portion of the total phenotypic variance) is unknown and may well be small, the potential power of these recombinant DNA techniques argues against any premature judgement that complex behavioural traits with non-Mendelian patterns of inheritance are necessarily polygenic in origin.

Finally, genetic linkage strategies may provide an elegant means of 'validating' some diagnostic categories in psychiatry. The outcome of such a validation might be the delineation of 'families' of related disorders that have the same underlying vulnerability but differing phenotypic expression. Tracing the range of phenotypic expression for specific disorders from childhood on will be a particularly important undertaking for investigators interested in the possible continuities between adult and child psychopathology. Pathognomonic symptoms may be identified that may have relatively little clinical significance but which are highly associated with the underlying vulnerability. It will also permit the identification of phenotypically similar but aetiologically distinct disorders which can confound empirical psychiatric research.

The Newcastle Adolescent Behaviour Screening Questionnaire

M. PLACE, I. KOLVIN and S. M. MORTON

As part of a larger study, a brief rating-scale was developed which focusses on the mid-adolescent phase of development. Completed by teachers, the questionnaire has an inter-rater reliability of 0.78, with a test–retest correlation of 0.82. When the performances of various screening instruments were compared it became clear that no single questionnaire was obviously more efficient than the others at detecting potential disturbance in an urban adolescent population. Indeed, different questionnaires seemed to highlight particular facets of functioning. The Newcastle Adolescent Questionnaire proved to be a reliable and valid screening measure.

Several teacher questionnaires measure facets of the behaviour of children and adolescents. Some of these questionnaires are standardised for specific stages of development, e.g. the Devereux Scale (Spivack *et al*, 1967), while others are used across the whole school age-range with only minor attempts to standardise for age (Rutter, 1967; Conners, 1969). The Rutter B2 Scale consists of 26 items and gives rise to two sub-scales, neurotic and antisocial behaviour, while the Conners Scale consists of 39 items and generates four sub-scales: inattentive–passive; passivity; anxiety; and hyperactivity. The Behaviour Problem Checklist (Quay & Peterson, 1979) consists of 55 items and also generates four factors. Although this instrument has been well validated, especially in the younger age-group, the factors show a bias toward detecting conduct and personality problems, so that the checklist may miss a portion of the distressed adolescents in the community (Place & Kolvin, in preparation). One of the few scales which is specific for adolescence is the Adolescent Life Assessment Checklist (Gleser *et al*, 1977), but this 40-item scale has only been validated for selected samples (Boyle & Jones, 1985) and so its value as a community screening instrument is unclear.

As part of a larger study, it was decided to develop a questionnaire which would be very brief and would focus on the mid-adolescent phase of development. Using clinical experience and published reports, we considered a large number of behavioural features for inclusion. Seven were eventually chosen because they often give rise to concern in educational settings: they include a sense of confusion, excessive day-dreaming, lability of mood and emotion, lack of confidence, and being easily upset in the face of educational failure (see Figure 1). In addition it was decided to include three more global ratings. The first reflects more widespread neurotic behaviour, the second antisocial behaviour. As a final item we decided to include educational difficulties which were serious enough to warrant special attention. We suspected that a positive rating on this item would prove a useful indicator not only of general educational difficulties but also of personal and interpersonal problems.

The aim of the current paper is to explore the use of this brief questionnaire in an adolescent sample drawn from the community. Our primary hypothesis was that adolescents detected as being potentially disturbed using a 'multiple-criterion screening' technique (described below in the 'Method' section) would prove to have significantly high scores on this brief questionnaire. This would in effect provide a form of validation of the questionnaire. A second aim was to study its sensitivity and specificity compared with a psychiatric interview. Finally, it was planned to compare the scores obtained on this instrument with the scores obtained on longer screening questionnaires by the same population.

Method

The 4th and 5th-year pupils of four large comprehensive schools agreed to participate in the study: 1446 adolescents formed the population for this phase of the study, and they were screened using a 'multiple-criterion screen' method. This technique uses the number of extreme scores that an individual obtains on a variety of instruments as a measure of potential disturbance. The detailed methodology may be found elsewhere (Place *et al*, 1985), but in brief the screen consisted of:

(a) Rutter B2 Scale (Rutter, 1967, 1973)
(b) a sociometric assessment technique (MacMillan *et al*, 1978)

Newcastle Adolescent Behaviour Questionnaire

Name of Child .... School..........

Date of Birth .... Form ....

Below are a series of questions describing behaviour often seen in adolescents. If the description applies to this youth please mark the third column. If it does not apply please mark in the first column. If it applies to a lesser degree please put a cross in the box in column two.
Please consider only recent behaviour, i.e. in the last 6 months.

	No	Somewhat	Yes	For Official Use Only
1. Excessive day dreaming	☐	☐	☐	☐
2. Often looks puzzled or confused	☐	☐	☐	☐
3. Over-emotional when checked or frustrated	☐	☐	☐	☐
4. Lacks confidence in educational situations	☐	☐	☐	☐
5. Tends to vary in mood	☐	☐	☐	☐
6. Easily upset when cannot master educational tasks	☐	☐	☐	☐
7. Reserved and uncommunicative	☐	☐	☐	☐

It would be most helpful if you could make an overall assessment as to whether this youth:

	No	Somewhat	Yes	For Official Use Only
is nervous, i.e. emotional, tense, worried and anxious, to the extent of impeding him in his school work or relationships	☐	☐	☐	☐
shows problem behaviour, i.e. difficult and disruptive behaviour, disobedient, etc.	☐	☐	☐	☐
has educational difficulties which merit special attention	☐	☐	☐	☐

(c) Junior Eysenck Personality Inventory (Eysenck, 1965)
(d) General Health Questionnaire (Goldberg, 1972)
(e) Rutter Malaise Inventory (Rutter *et al*, 1970).

(a) Rutter B2 Scale This is a teacher-report instrument which has been used in many settings, both in this country (Ryle & MacDonald, 1977; Rutter, 1973; Wolkind, 1974; MacMillan *et al*, 1980) and abroad (Minde, 1975; Zimmermann-Tansella *et al*, 1978). The instrument was designed for the 6–13 age-group (Rutter, 1967), for whom it has an inter-rater reliability of 0.72 and test–retest reliability of 0.89. Little validation work has been carried out on the instrument in the adolescent age-group.

(b) Sociometry This technique uses the responses of peers to gauge an individual's social standing. It allows identification of those youths who are likely to be avoided by classmates (rejection) and those who would not be chosen as friends (isolation). It has been shown to be a rapid way of gathering useful information from younger children (MacMillan *et al*, 1978) with a test–retest reliability of 0.87 for rejection and 0.72 for isolation (tests carried out 4–5 weeks apart), but its effectiveness with adolescents seems less clear (Place & Kolvin, in preparation).

(c) Self-Report The Junior Eysenck Personality Inventory (Eysenck, 1965) was used as the main item of self-report, although previous work with 11-year-olds has shown that it tends to select a rather unique population compared with other measures (MacMillan *et al*, 1980). The neuroticism scale is reported to have a split-half reliability of 0.84 and a test–retest reliability of 0.77 (Eysenck, 1965).

In addition, 605 youths completed the 30-item General Health Questionnaire (Goldberg, 1972) and 1237 completed the Rutter Malaise Inventory, which has a test–retest reliability of 0.91 (Rutter *et al*, 1970). In an effort to reduce the workload on teachers and also to minimise the disruption of classes for the pupils, all were tested, but not everyone with all the tests. This also ensured that the exercise remained within the resources of the research team.

The next step was to compare the results obtained from the questionnaire with the data obtained from a psychiatric interview. For these purposes a sub-sample of 82 youths

TABLE I

*Correlation of items in the Newcastle Adolescent Behaviour Questionnaire. All correlations are significant at the 0.001 level, except for * ($P < 0.05$)*

	A	B	C	D	E	F	G	H	I	J	K
A. Educational difficulties	1.0										
B. Disruptive and disobedient	0.16	1.0									
C. Tense, worried and anxious	0.43	0.14	1.0								
D. Reserved and uncommunicative	0.25	0.06*	0.39	1.0							
E. Easily upset	0.29	0.37	0.42	0.2	1.0						
F. Variable mood	0.17	0.58	0.27	0.11	0.53	1.0					
G. Lacks confidence	0.44	0.18	0.44	0.43	0.47	0.32	1.0				
H. Overemotional	0.22	0.58	0.28	0.08	0.58	0.68	0.29	1.0			
I. Puzzled	0.42	0.13	0.38	0.38	0.38	0.26	0.66	0.25	1.0		
J. Day dreams	0.36	0.19	0.39	0.43	0.29	0.28	0.52	0.25	0.61	1.0	
K. Total Score	0.56	0.51	0.63	0.54	0.69	0.65	0.76	0.64	0.72	0.69	1.0

was selected on a random basis from the youths who had an extreme score on at least one of the four screening instruments. The percentage levels used for cut-off were varied to ensure the inclusion of at least 20 individuals on each major criterion, but because of overlap the number selected on each was approximately 30. In addition, 50 adolescents were selected at random from the youths who had no extreme scores on any of the measures. All of these 132 youths were given a structured psychiatric interview, the interviewer being unaware of the questionnaire results. Psychiatric disturbance was rated as 'absent', 'dubious', 'moderate' or 'marked' and these ratings were then further combined to produce two groups—'no significant disturbance' (absent/dubious) and 'significant disturbance' (moderate/marked).

For comparison, 30 adolescents who were resident in a medium-stay psychiatric unit were assessed with the instruments mentioned above, with the exception of the sociometric technique. Additional data were obtained from the teachers of this in-patient group to allow a study of the Newcastle Questionnaire's inter-rater and test–retest reliabilities to be undertaken: two of the teachers were asked to rate the youths' behaviour at the time of the survey and again one month later.

Results

It is important to establish the reliability and validity of any new behavioural measure, and this may be done in various ways.

Reliability

(a) Inter-rater reliability

It is necessary to confirm that different teachers will give similar ratings for similar behaviour. Greater agreement occurs when the instructions on the use of the instrument are carefully presented in a standard form, and it was for this reason that we chose to follow the presentation used by Rutter in his teacher questionnaire (Rutter, 1967). To test reliability we used the 30 adolescent patients in a medium-stay psychiatric unit: community surveys yield small numbers of potentially disturbed youths and so the correlations found may be influenced by a lack of spread in the data. The questionnaire's inter-rater reliability was found to be 0.78 ($n = 30$), which is satisfactory for this kind of brief instrument.

(b) Test–Retest reliability

This was established using the same 30 in-patients as for inter-rater reliability: they were reassessed after one month. Such exercises, which are essential to test the reliability of an instrument, are often bedevilled by the variation of behaviour which occurs over time. Nevertheless, the correlation value obtained (0.82) is an acceptable one for this type of screening instrument.

(c) Split-half reliability

After pairing items, one member of the pair was assigned randomly to either the first or second half of the questionnaire. A Pearson correlation of 0.84 was obtained between these halves, and applying the Spearman Brown Prophecy formula the split-half reliability was calculated at 0.91. This is a highly satisfactory level of reliability for a scale of 10 items, particularly as one of the items is not intended to measure behaviour directly.

To confirm this finding, the split-half reliability exercise was repeated without the more global assessments being included. This yielded a Pearson correlation coefficient of 0.85, which is almost identical to the value obtained for the full scale.

In addition, the means and standard deviations of the split-halves were calculated, and proved to be almost identical, indicating that they are equivalent measures of behaviour.

TABLE II

Validation: mean scores on the Newcastle Adolescent Behaviour Questionnaire for three different groups selected using other previously validated screening instruments

	A *Controls (screen –)*	B *Screen +*	C *Psychiatric in-patients*
n	1144	302	30
Mean	1.99	3.98	6.87
s.d.	2.73	3.94	3.35
Significance (*t*-test)	A *vs* B $t = 10.2$ $P < 0.0001$	B *vs* C $t = 3.88$ $P < 0.001$	
		A *vs* C $t = 7.91$ $P < 0.0001$	

Validity

(a) Content validity

Content validity is usually taken to mean that the items reflect the type of behaviour that the instrument is intended to measure. We believe the items chosen for this instrument have face validity. However, their relationship to each other and to the total score was explored. As Table I shows, although some of the correlations are reasonably high and some are low, all the correlations are positive. The average inter-correlation of the items was 0.34, and this suggests that the items are measuring similar aspects of behaviour. Cronbach has developed a formula for assessing the internal consistency of a questionnaire (Bynner, 1969), which provides a coefficient based on the average correlation between items and the number of items used. For an instrument to have valid internal consistency the Cronbach coefficient should be more than 0.5. The present scale gives a coefficient of 0.69, which is satisfactory.

(b) Concurrent validity

This compares the scores obtained on the scale with an external criterion, either information obtained from a clinical interview or scores on other instruments which are known to be valid. We explored our instrument's ability to distinguish between three groups of youths:

A. Controls Youths who did not emerge as high scorers on a number of previously validated instruments of child disturbance, i.e. youths who were 'screen negative'.

B. Screen positives Youths with a number of extreme scores on previously validated instruments designed to detect disturbed behaviour.

C. Psychiatric cases Adolescents whose difficulties were so severe as to not permit them to survive in the community and so warranted admission to a psychiatric unit on an in-patient basis. These youths could be expected to be more disturbed than the screen-positive adolescents who were surviving in the community.

Table II demonstrates a highly significant step-by-step increase in mean score on the questionnaire as we move from group A (the least disturbed) to group C (the most disturbed).

Table III gives teachers' ratings on the individual questions for each of these three groups, and confirms that all the questions distinguished between the controls and the potentially disturbed subjects. Such a finding adds further to the conclusion that the Newcastle Adolescent Behaviour Questionnaire is a valid instrument for an urban adolescent population.

(c) Sensitivity, specificity and efficiency

Cut-off scores of 3, 4, 5 and 6 on the Newcastle Questionnaire were explored in relation to the findings on the psychiatric assessment, and it was established that a score of 4 or more proved to be optimal for identifying potential cases in this particular population. Such an exploration tests the validity of the questionnaire at each particular cut-off score: it checks the proportion of 'correct' cases the instrument detects against the proportion it misses (*sensitivity*); the proportion of true negatives it correctly identifies (*specificity*); and the proportion of correct selection in the sample as a whole (*efficiency*).

The method of selecting the interview sample did not permit direct inferences about the total study population. The number of disturbed adolescents in the total sample was estimated from the proportion of disturbed youths found at each score in the interview sample. This estimate was then used to explore the performance of the questionnaire when the optimum cut-off was used (Table IV). Our method of calculating sensitivity, specificity and efficiency is detailed elsewhere (Place *et al*, 1985). The results reveal that the instrument is capable of selecting potential cases of adolescent disturbance with a moderate degree of accuracy, but is far less efficient than the Behaviour Screening Instrument developed by Richman & Graham (1971) for pre-schoolers, particularly in terms of specificity, and less efficient than scales developed for adult populations (Goldberg, 1972).

Comparison with other measures

In order to establish the comparative efficiency of this measure compared with other available scales which might be considered appropriate for screening adolescents, all the instruments were compared using their estimated performance in the study population when the optimum cut-off was used: the sensitivity, specificity and misclassification rate were established for each instrument. This is a rather crude analysis, but it showed that no instrument was clearly superior to the others. The sociometry scales showed a low sensitivity (isolation 30%, rejection 19%); highest were the Malaise Inventory (61%) and General Health Question-

TABLE III
Validation: percentage of high scores on each question of the Newcastle Adolescent Behaviour for each of three different groups (selected with previously validated screening instruments)

TABLE IV
Efficiency of the Newcastle Adolescent Behaviour Questionnaire in identifying cases in an adolescent population, compared with the estimated prevalence of disturbance. For these calculations the optimum cut-off score was used (4 or above)

	n	*Sensitivity*	*Specificity*	*Misclassification*	*κ*
Total population	1446	51%	82%	26%	0.32
Boys	745	57%	83%	23%	0.38
Girls	701	46%	80%	30%	0.26

naire (57%). The Newcastle scale fell in-between, with 51%. Although the Rutter B2 Scale was not very sensitive (32%), it had a lower misclassification rate (22%) than the Newcastle Scale (26%). The performance of the Rutter B2 Scale in this population shows that some of the items were not as sensitive at this age-level as they had been in the younger age-group.

The Newcastle Questionnaire scores were correlated with the scores obtained on the other measures, and for comparison the exercise was repeated for the Rutter B2 Scale (Table V). The significant correlations are with the peer-report measures and they are low; but they are of the same order as those obtained by the Rutter B2 Scale. The inter-correlation of the Newcastle Adolescent Questionnaire and the Rutter B2 Scale gives a reasonably high coefficient (0.69) which suggests that the two scales have much in common. There is a moderate but statistically significant correlation between the Newcastle Questionnaire and the multiple-criterion screen score. It is lower than the correlation between the multiple-criterion screen score and the B2 Scale, but the B2 Scale contributes to the screening procedure and so a high correlation is to be expected.

Comparing the Newcastle and Rutter B2 Scales (both teacher-report instruments) with questionnaires which explore other facets of functioning, we can clearly see that correlation between some of the scales is poor. It has been pointed out elsewhere (MacMillan *et al*, 1980) that the Junior Eysenck PI neuroticism scale has little in common with other screening measures for 11-year-old subjects, and it is perhaps not surprising to find a similar result in adolescence. However, all the self-report inventories correlate well with each other, and they show equal validity when compared with a psychiatrist's assessment (Place & Kolvin, in preparation). If we assume that these inventories are tapping internalised distress, there seems little doubt that the potential cases that they select are likely to be distinct from those who have shown behaviour problems at school. This distinction between internalised distress and externalised problems of conduct is not new (Rutter *et al*, 1970), but cannot be tapped in adolescence unless specific questionnaires are used. If this is not done, any survey tends to reflect objective behaviour problems and show minimal internal climate problems. With such little overlap between scales which measure such functions, the importance of using both sources of information is reaffirmed.

The Newcastle scale appears to be more sensitive for boys

TABLE V
Correlations of Newcastle Adolescent Behaviour Questionnaire and Rutter B2 Scale with other measures of adolescent behaviour

	Newcastle	*Rutter B2*
Multiple-criterion screen	0.33*	0.55*
Sociometry[1]		
Isolation	0.19*	0.21*
Rejection	0.19*	0.20*

than for girls, a finding which is supported by the higher kappa score (Table IV). When considered with the above findings this suggests the hypothesis that behaviour scales may be more accurate at detecting disturbed boys while self-report measures may be more accurate at detecting disturbed girls. Such a theory is discussed in more detail elsewhere (Place & Kolvin, in preparation).

Discussion

New rating scales seem to appear frequently, and disappear almost as quickly. Snaith (1981) has urged that existing measures be refined and improved rather than perpetuating the development of more and more new instruments. This is a most appropriate aspiration because the response to a rating scale must be considered in the light of various factors.

'Overall Agreement Set' (Cronbach, 1942) identifies respondents' desire to give the answer that is expected or at least which appears less critical of themselves. This may be a particular problem in school-based research which uses the teachers as a source of information, when the results may be used to assess a school's ability to educate and control (Rutter *et al*, 1979; Rutter 1980). Despite this limitation many surveys have depended upon school-based research (e.g. Rutter *et al*, 1970; Offer, 1969; Coleman, 1974; Newman 1979) because, as Lewine *et al* (1978) have pointed out, "teachers are capable of making sophisticated and valuable observations regarding the psychological adjustment of their students". In addition, this type of research is popular with epidemiologists because the number of 'missing cases' is lower than with other methods of identifying a population: this advantage may be reduced in an adolescent population, however, because absentee rates tend to be high in this age-group (Fogelman *et al*, 1980).

In screening populations it is usual to seek a brief measure which is reliable and valid and of low cost (Boyle & Jones, 1985). Such a measure is already available for pre-school children (BSQ: Richman & Graham, 1971). The Rutter B2 Scale is a well-established instrument for use with school children but is not specific for adolescents. The Newcastle Adolescent Behaviour Questionnaire has been developed in an attempt to fill this gap, but its advantages over the Rutter B2 Scale, other than brevity, have yet to be established. However, its very brevity makes it suitable for investigating large populations.

One area of concern is the high misclassification rate which is obtained when this instrument's scores are compared with the findings at psychiatric interview. However, the other instruments tested show a similar range of misclassification values. Although some authors report minimal misclassification rates (Goldberg, 1972), others have obtained rates similar to those reported here when studying urban community populations (Tarnopolsky *et al*, 1979).

The lack of correlation between the self-report measures and the teacher-assessed scales could reflect a lack of validity in the new scale or could indicate that the self-rating scales are measuring different components of behaviour. Since the lack of correlation is similar for the well-validated Rutter B2 Scale, and with evidence of the validity of the self-report measures being available, it seems likely that the different types of instrument are detecting different components of behaviour.

Goldberg (1972) has pointed out that when screening a population research workers assume that psychiatric disturbance is evenly distributed throughout the population in varying degrees of severity. An individual's score on a questionnaire may then be seen as a quantitative estimate of that individual's degree of potential disturbance. These assumptions allow the researcher to decide upon a limit score, or cut-off, such that subjects with scores above it have a high probability of showing disturbance. However, like most screening instruments, such a questionnaire is not intended to make diagnostic distinctions.

Our results indicate that no single screening instrument is superior for detecting potential disturbance in adolescence. Indeed, different questionnaires seem to highlight particular facets of functioning, which are not necessarily detected by the others. Behavioural measures must sample both internal and external qualities if they are to fully explore disturbance in an adolescent population. The Newcastle Adolescent Questionnaire, although very brief, has proved to be almost as reliable and as valid as most of the other screening instruments available for this age-group.

Affective Illness After Stroke

S. EBRAHIM, D. BARER and F. NOURI

Mood assessments were made after six months of 149 survivors taken from a register of all patients admitted to hospital with acute stroke. Using a General Health Questionnaire score of 12 or more as a criterion of important affective illness, its prevalence was 23%. There was no difference in risk of affective illness between left and right hemisphere strokes. Affective illness was strongly associated with functional ability, with limb weakness and with longer hospital stay in those with good functional recovery. Only 15% of those with high scores were receiving antidepressant drugs. The general practitioner is in the best position to detect psychiatric illness in stroke survivors; the use of mood rating scales such as the GHQ, in conjunction with clinical assessment, may improve detection.

Although depression is well recognised as a barrier to recovery after stroke (Adams & Hurwitz, 1963) and occurs commonly in selected groups (Robinson & Price, 1982; Robinson *et al*, 1984*a*), it is frequently missed in practice (Fiebel *et al*, 1979). Robinson & Price (1982) assessed mood at various stages after a stroke in selected groups of referred patients and in a small prospective study (Robinson *et al*, 1983). In the latter study the majority of the patients were relatively young, working class and black. No representative series reflecting the age and ethnic structure of the contemporary British population has been studied.

We chose to use the General Health Questionnaire (GHQ) to assess mood as it is easy to use, has been well validated (Goldberg & Hillier, 1979), has previously been used with stroke patients, and compares well with other mood assessments (Robinson & Price, 1982). We aimed to measure the prevalence of affective illness six months after an acute stroke in patients admitted to hospital, observing possible associated factors such as the site and severity of stroke, length of hospital stay, and degree of functional recovery. Finally, we assessed the opportunities for detection and treatment of post-stroke affective illness.

Method

All patients admitted to Nottingham hospitals with an acute stroke over an eight month period were followed up. Clinical information was collected on admission, and at one and six months afterwards, but mood was assessed by GHQ at six months only. Follow-up assessments were performed by a single observer. Neuroradiological investigations were not routinely available, so in most cases the diagnosis and location of the lesion were made clinically, using the World Health Organisation (1978) definition of stroke: 'Rapidly developing clinical signs of focal or global disturbance of cerebral function, lasting more than 24 hours, or leading to death, with no apparent cause other than of vascular origin'.

Severity of motor impairment was measured by summing scores for each affected limb (normal = 1, some weakness = 2, complete paralysis = 3). Patients' functional ability was assessed using the following activities of daily living (ADL): drinking, feeding, washing, transfers from bed to chair, walking, dressing, undressing, using the toilet, making a hot drink and bathing. Patients scored one point for each activity done independently (with or without aids) and zero if help or verbal prompting were required. A score of 10 indicated ability to carry out all the items, and a score of zero none of them. This has been shown to constitute a ranked ordinal scale, so that comparisons can be made even between patients with different kinds of disability (Ebrahim *et al*, 1985). The Mini Mental State examination (Folstein *et al*, 1975) was used to assess cognitive ability; patients with a score of less than 10 out of 30 were excluded from the study. To assess mood at six months a GHQ form was posted to each patient to fill in; this was collected by the interviewer during the home visit.

The GHQ consists of four component scales: somatic symptoms, anxiety and insomnia, social dysfunction and severe depression. Although a GHQ score of 5 or more (out of 28) is usually taken to indicate clinically important illness (Goldberg & Hillier, 1979), a score of 12 or greater is more appropriate for use with patients with physical illness (Bridges & Goldberg, 1984).

The non-parametric significance tests (Mann-Whitney U, Kruskal-Wallis ANOVA, and chi-squared) were used to examine differences between groups.

Results

During the eight month study period 463 cases of acute stroke were registered. Of these, 235 (51%) survived for six months, and all but 13 were followed up (eight had moved

1. Kruskal-Wallis ANOVA test.

out of the area or could not be traced, and five refused follow-up). Assessment was not possible in some cases: 26 were dysphasic, 17 were too cognitively impaired, and 13 who were still in hospital could not be assessed in the same manner as those at home. Seventeen patients living at home did not receive a GHQ because of administrative errors. This latter group did not differ significantly in terms of age and sex distribution, functional ability or side of stroke from the rest. The final study sample was composed of 149 patients, all of whom were living at home, Their mean age was 69 years; 76 (51%) were men, 82 (55%) were married and 46 (31%) were living alone; 137 (92%) were living in their own homes, and the remainder were in sheltered accommodation. For the majority (84%) this was their first stroke.

Thirty four (23%) patients had GHQ scores of 12 or more, and all but two of them scored on the 'severe depression' component of the GHQ; two-thirds answered positively to three or more of the seven 'severe depression' questions. There were high levels of correlation (from +0.75 to +0.85) between the four GHQ component scales and the total score.

Laterality and affective illness

The distribution of GHQ scores for different types of stroke is shown in Table I. There was no significant difference in mean GHQ scores between left and right hemisphere strokes. Of those patients who were unable to walk at six months, three out of seven with left hemisphere strokes and four out of nine with right hemisphere strokes had scores of 12 or more. Of 38 patients who were dysphasic on admission but who improved enough to be assessed at six months, 9 (24%) had scores of 12 or more, compared with 25 (22%) of the 111 without speech problems.

Associations with disability and other factors

Strong relationships between GHQ score at six months and functional ability at both one and six months after onset of stroke and an association with motor impairment were found (Table II). Among seven patients whose disability increased between one and six months, three had high GHQ scores of 12 or more. Nineteen (25%) out of 76 patients whose ability improved had high scores, compared with 12 (18%) out of 66 patients whose ability did not change ($P<0.05$).

Functional ability at six months was strongly associated with length of hospital stay (Spearman $r=-0.55$, $P<0.001$), as was GHQ score at six months (Spearman $r=0.21$, $P<0.01$). Of 21 patients with a GHQ score of 12 or more, but with good functional recovery (ADL score of 9 or 10 at six months), 13 (62%) stayed in hospital longer than the median stay of 1/.4 days compared with 46 (47%) out of 98 patients with GHQ scores below 12 ($Z=2.31$, $P<0.05$). The GHQ score did not correlate with length of stay for patients with poorer functional recovery. Patients with sensory inattention also had higher scores ($Z=3.01$, $P<0.01$) but when disability was controlled for there was no association.

Age, sex, marital status, living alone and previous stroke showed no association with the GHQ score. Six out of 34 (18%) patients with scores of 12 or more were incontinent of urine, compared with 13 out of 115 (11%) with low scores. Significantly more patients with high GHQ scores had had impaired mobility (18%) and had been on antidepressants (6%) before their stroke.

Use of services

Patients with high GHQ scores saw the district nurse and social worker significantly less often than those with low scores, but the differences in frequency of family doctor visits (78, 52% overall) and out-patient attendance (48, 32% overall) were not significant. Only five (15%) patients with high GHQ scores were being treated with antidepressants at six months.

Discussion

The GHQ agrees well with other questionnaires used to assess depressed mood (correlation coefficients: $r=+0.86$, Zung; $r=+0.88$, Hamilton; $r=+0.94$, Present State Examination – Robinson & Price, 1982), although it may tend to overestimate the prevalence of affective illness as physical disability can contribute to the 'social dysfunction' component. Using a higher cut-off of 12 or more, as recommended by Bridges & Goldberg (1984), reduces this tendency, but increases the likelihood of missing cases. Twenty-three per cent of survivors had GHQ scores of 12 or more six months after their stroke, indicating a high probability of affective illness. It is not possible to compute estimates of the true prevalence of affective illness, as outlined by Bridges & Goldberg (1984), because measures of the accuracy of the GHQ for this type of patient are not available. If GHQ accuracy is low (ie. sensitivity and specificity about 80%) then the likely true prevalence of affective illness will be very low – about 5%. However, if the sensitivity and specificity of the GHQ are similar to values obtained from community studies (ie. sensitivity and specificity about 86%), the estimated prevalence of affective illness is 44%.

It is likely that most of the patients with high scores were suffering from depression, as so many of them answered positively to questions about severe depression. Furthermore, Bridges & Goldberg (1984) showed that the majority of in-patients suffering from neurological illness with scores of 12 or more did have depression or mixed depression and anxiety states, when compared with standardised psychiatric assessments.

Robinson & Price (1982) found that 23% of their patients had GHQ scores of 6 or more out of 28, but some were seen up to 10 years after their stroke, by which time symptoms might well have resolved. In another study Robinson *et al* (1984*a*), using different diagnostic methods, classified 30 of 50 patients seen six months after stroke as depressed. However, less than two thirds of the original cohort were assessed. Just over a third of those seen were labelled as suffering from major depression by DSM—III criteria (American Psychiatric Association, 1980) and this is comparable with the 23% of our group with GHQ scores of 12 or more.

Laterality and affective illness

Losses and life events are known to be important causes of depression in the elderly, and post-stroke depression may well be a reaction to loss of physical health and function (Murphy, 1982). However, Folstein *et al* (1977) found that stroke was more likely to be associated with depression than orthopaedic disability of similar severity. Robinson & Coyle (1980) have put forward an alternative hypothesis based on the catecholamine depletion that can follow diffuse or focal brain injury. They and others (Dimond *et al*, 1976; Giainotti, 1972) have shown that right hemisphere damage is more frequently associated with these biochemical changes in the rat and suggest that this may be associated with clinical depression seen in humans after stroke.

We found a strong relationship between the degree of physical disability and the likelihood of a high GHQ score, but no significant difference between left and right hemisphere lesions after controlling for degree of disability. A recent study by Robinson *et al* (1984*b*) showed an increase in depression scores with proximity to the left frontal pole and an inverse relationship for right hemisphere lesions. The strength of these associations depended on very small numbers of patients with very high and very low depression scores; thus they could well have been spurious. In contrast, Folstein *et al* (1977) demonstrated an excess of depression among patients with right rather than left hemisphere lesions. Lishman

(1968) studied 670 patients with traumatic penetrating lesions caused by bullets or shell fragments during World War II. He showed that among 113 patients with affective disorders, depressive symptoms and poor concentration were commoner with right hemisphere damage, particularly in the frontal and parietal regions.

Depression may often be missed in patients with left hemisphere strokes because of dysphasia; certainly fewer of these patients receive antidepressant treatment (Lim & Ebrahim, 1983). Exclusion of dysphasic patients from study at six months may have caused a biased assessment of the relationship of side of lesion with mood disturbance, but it is of interest that those patients initially suffering with dysphasia were no more likely to have a high GHQ score than those without speech disorder. It is probably unwise to generalise about mood disturbance from dysphasics who recovered their speech to those who did not, but out study is no more biased in this respect than others and had sufficient power to detect an important difference in laterality and mood disturbance.

Associations with disability

The link between stroke severity and likelihood of affective illness has not been a consistent finding in other studies. Robinson *et al* (1982, 1983) found no relationship with functional ability among 'chronic' stroke patients and no association with volume of brain damage (1984*b*). The numbers in our study were much larger, and the increased frequency of high GHQ scores in those whose physical disability increased between one and six months, and the association with degree of motor impairment both suggest that stroke severity and mood disturbance are strongly related. It is unlikely that the GHQ scores were merely mirroring physical disability, since patients with intermediate (6–11) scores and those with high (12 or more) scores had very similar levels of physical disability (see Table II).

Although our study was organised on a prospective basis, the GHQ was only used at the six month follow-up. Thus we are not able directly to assess the effect of affective illness on other outcomes. Nevertheless, as mood disturbance is likely to have been present soon after onset of a stroke (Robinson *et al*, 1984*a*), the positive association between GHQ score and time spent in hospital is likely to be causal. Depression is a recognised cause of failure of rehabilitation (Adams & Hurwitz, 1963) and we have shown that high GHQ scores contribute to longer hospital stays for patients with relatively minor functional disability. Patients with major disability stay in hospital much longer and mood disturbance does not appear to influence this.

Use of services

General practitioners have the greatest opportunity for detection of affective illness after stroke, as between 70% and 90% of patients aged over 65 are seen in any year by their general practitioner (Royal College of General Practitioners, 1974). Over half of the patients in our series had been seen in the month prior to interview. Nevertheless, only five (15%) patients with high GHQ scores were taking antidepressant drugs, despite evidence of efficacy in certain categories of patients (Lipsey *et al*, 1984; Rosen and Martorano, 1965). Increased awareness of post-stroke affective illness by doctors and therapists will help in providing support for both the patient and the family.

rescribing Information ▼ **Presentation:** Round, yellow, enteric-coated tablets each
mg fluvoxamine maleate, imprinted with 'Duphar 291'. Pack of 60 tablets, basic NHS price
s: Treatment of those affective disorders characterised by persistent low mood, impaired
activities and psychosomatic complaints. **Dosage and Administration:** The tablets should
without chewing and with water. Adults: The effective daily dose usually varies between
00mg and should be adjusted to the individual response of the patient up to a maximum of
minimum recommended starting dose is 100mg given in the evening. A total daily dosage in
mg should be given in divided doses. Elderly: The same dosage regimen may be utilised in the
he general population. Children: There are insufficient data to recommend the use of Faverin in
tra-indications, Warnings, etc: Faverin should not be given together with or within two
rminating treatment with monoamine-oxidase inhibitors. Patients with hepatic or renal
should begin treatment with a low dose and be carefully monitored. Faverin has no effect on
skills associated with driving and operating machinery. However, in combination with alcohol
nent may be seen. Use in pregnancy and lactation: There has been little human use but there
adverse animal evidence. Avoid in pregnancy and in nursing mothers if a better known and safer
available, although safety in pregnancy is likely. Interactions with other drugs: In interaction
studies increased plasma levels of propranolol and warfarin were seen during concurrent administra
Faverin. Care should be taken when Faverin is prescribed to patients already receiving propranol
warfarin as the dose of these drugs may need to be lowered. No interactions were seen with digoxin
atenolol. **Side-effects:** The commonest symptom observed with Faverin administration is nausea
usually diminishes early during the course of treatment. Other treatment emergent symptoms re
during clinical studies were somnolence, constipation, agitation, anorexia and tremor. Other reported
are often associated with the illness and their incidence in controlled trials is comparable t
experienced with placebo. Faverin may cause a decrease in heart rate. During treatment, limited chan
repolarization were observed in the ECG, but no causal relationship could be demonstrated. The incide
postural hypotension was similar to that seen in patients treated with placebo. Treatment of overdosa
specific antidote is known. The stomach should be emptied as soon as possible after tablet ingesti
symptomatic treatment should be given. The use of medicinal charcoal is also recommended. **Pa**
Quantities 50mg tablets: available in packs of 60 (3 strips of 20 blister-packed tablets). **Product Li**

FAVERIN®
fluvoxamine

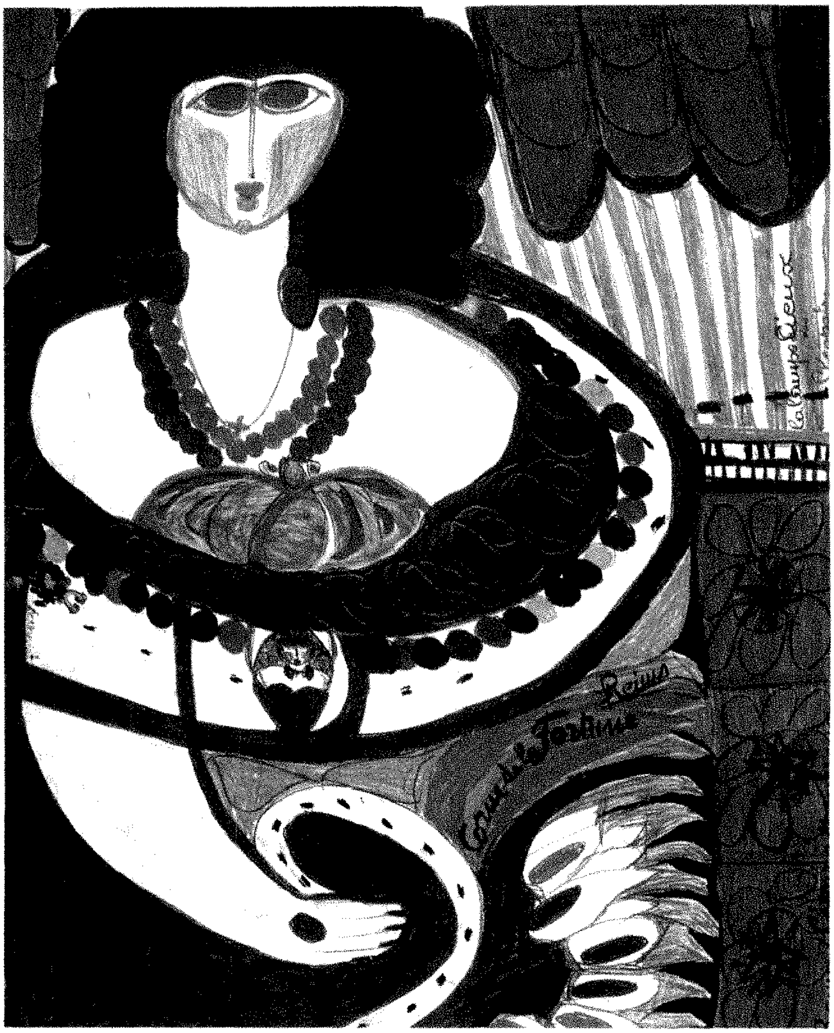
Highly Selective 5-HT Reuptake Inhibitor

AN EXPRESSION OF SCHIZOPHRENIA.

Aloise was diagnosed as schizophrenic at the Cery Asylum, Lausanne. She was later transferred to the Asylum de la Rosiere where she remained for over 40 years until her death in 1964.

During the last 20 years of her life she worked steadily at her drawings.

The illustration below is produced with kind permission of the Musee Cantonal Beaux-Arts, Lausanne.



A TREATMENT.

Since the 1950s when Dr Paul Janssen and co-workers researched and developed the prototype butyrophenone halopheridol, it has become widely established throughout the world as an effective anti-psychotic. In 1982 Haldol* Decanoate was introduced to the UK as a depot neuroleptic with a consistent 4 week duration of action following a single deep intramuscular injection.

In mild symptomatology the dosage for Haldol* Decanoate is from 50-100mg given 4-weekly, whereas severe schizophrenic symptoms are usually controlled with up to 300mg.

The schizophrenic patient can benefit from a flexible therapy with little incidence of sedation[1] and a reduced requirement for antiparkinsonian medication,[2] leaving him/her better able to participate in other forms of therapy.

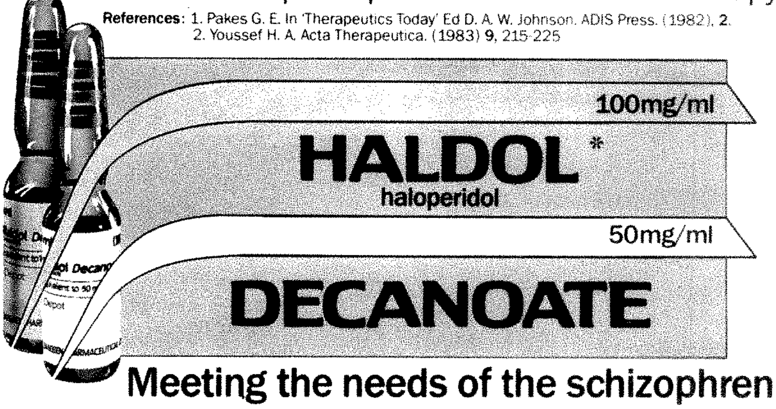
2. Youssef H. A. Acta Therapeutica. (1983) **9**, 215-225



Meeting the needs of the schizophrenic.

Presentation: Straw coloured, viscous solution presented in 1ml brown glass ampoules equivalent to 100mg/ml haloperidol (as decanoate ester) and 1ml brown glass ampoules equivalent to 50mg/ml haloperidol (as decanoate ester) both in packs of 5. **Uses**: As a depot injectable form of haloperidol indicated for adults where long term maintenance treatment with a neuroleptic is required, for example in schizophrenia, other psychoses (especially paranoid) and other mental or behavioural problems where maintenance treatment is clearly indicated. **Side effects, precautions, contra-indications**: Haloperidol is not recommended during lactation. Use in Pregnancy: The safety of haloperidol in human pregnancy has not been established. Precautions: Caution in liver disease, Parkinson's disease, phaeochromocytoma, thyrotoxicosis, epilepsy and conditions predisposing to epilepsy. Antagonism of adrenaline, guanethidine, phenindione, anti-Parkinson effects of levodopa and impairment of metabolism of tricyclic anti-depressants have been reported. Haloperidol may increase the effects of CNS depressant drugs, and enhanced CNS effects when combined with methyldopa have been reported. Neurotoxic reactions to combined treatment with lithium and haloperidol have been reported. Side effects: In common with all neuroleptics, the following side effects may be observed, sedation, extra-pyramidal symptoms, tardive dyskinesia, mental dullness, dizziness, headache, excitement, agitation, insomnia, hyperprolactinaemia, galactorrhoea, gynaecomastia, oligo- or amenorrhoea, hypotension. Gastro-intestinal symptoms and weight changes have been reported. Anti-Parkinson agents should only be given as required. The elderly are more susceptible to sedative/hypotensive effects. Occasional local reactions such as erythema, swelling or tender lumps have been reported. In common with other anti psychotics, haloperidol has been associated with rare cases of neuroleptic malignant syndrome. **Dosage**: Haldol* Decanoate provides one month's therapy following a single deep intra-muscular injection in the gluteal region. An initial dose of 50mg every 4 weeks is recommended increasing if necessary after 2 weeks by 50mg increments to 300mg every 4 weeks. The dosage should be tailored to suit the individual patient and to reflect previous oral dosage. In adults 100mg Haldol* Decanoate is approximately equal to 500mg chlorpromazine (or equivalent) per day. Caution is required with the elderly, starting doses of 12.5mg to 50mg monthly should be tried first. **Product Licence Numbers**: 0242/0095, 0242/0094 **Basic NHS Cost**: 1ml x 100mg/ml x 5 £24.00 1ml x 50mg/ml x 5 £15.60. (Correct at time of printing). Further information is available on request from: **Janssen Pharmaceutical Limited**, Grove, Wantage, Oxon OX12 0DQ.

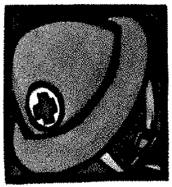
JANSSEN
PHARMACEUTICAL LTD

So what has Lilly ever done for Britain?



Well, where should we start?

The Second World War seems as good a place as any. By 1942 around one third of the production capacity of our newly-built Basingstoke factory was devoted to producing medicines for Britain's armed forces.

From foot powders to burn treatment, products manufactured by Lilly played their part in Britain's war effort.

Today we are contributing more than ever to Britain.

Our Part in Building Basingstoke

In 1939 we opened our first manufacturing plant in Britain, at Basingstoke. In those days the town had a population of less than 20,000. Today it is a busy commercial centre of 90,000 people.

As one of Basingstoke's biggest and longest-established employers, we are proud of our role in the town's growth and current success.

Just the Job for Liverpool

At Speke on Merseyside, our antibiotics processing plant provides much needed jobs for 900.

In fact, our Speke General Manager was recently awarded an OBE for his 'outstanding contribution to alleviating the problems of Merseyside.'

Add in our other UK operations, including our research centre in Surrey, and Lilly Industries Limited employs over 2,000 people throughout Britain.

The Health of the Nation

Leaving aside our contribution to the economy's well-being, we also do a considerable amount for the nation's health.

As one of the world's leading pharmaceutical companies, we have discovered and developed numerous important drugs.

An Indispensable Discovery from Lilly

It was Lilly who pioneered the Vinca Alkaloid group of compounds. These are widely used in Britain in the treatment of childhood leukaemia and are described by the Oxford Textbook of Medicine as 'indispensable.'

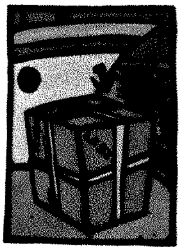
Thanks in part to this discovery, a condition that once almost always condemned young sufferers to death now has a vastly improved prognosis.

Then there was our work in the development of oral antibiotics. Before their introduction, administering antibiotics was a laborious and costly process. Expensive for the NHS and painful for the patient. With our help, the discomfort of both parties has been considerably lessened.

More recently, in 1982, we introduced genetically engineered human insulin manufactured in our plant in Speke. The benefit to patients with diabetes in Britain and around the world is unquestionable.

Where Research Becomes Reality

The success of our products is based, to a great extent, on research. UK research personnel located at our Erl Wood Research Centre in Surrey have contributed greatly to many of our worldwide projects, a prime example of Britain's expertise in the pharmaceutical field.



Exporting to the World

Lilly Industries Limited ranks among Britain's top exporters. Products manufactured here are distributed around the world, netting millions for Britain's balance of payments each year.

And what of profits? As an American company, do all the financial benefits wing their way back across the Atlantic? Not at all.

Investing in Britain

Our investment in Britain now tops over £140 million. In the last five years alone we have ploughed back £80 million. What is more, with our continued commitment to innovative pharmaceutical fields such as rDNA technology, we'll be spending a lot more in Britain in the next few years.

Employment, economic growth, investment and expertise. Just a few of the things an American pharmaceutical company has done for Britain.

The Outcome of Neurotic Disorders After Out-patient and Day Hospital Care

P. TYRER, M. REMINGTON and J. ALEXANDER

New psychiatric out-patients with depressive, phobic, and anxiety neurosis were randomly allocated to out-patient care or to one of two types of day hospital treatment, one specialising in psychotherapy and the other offering all forms of day care. Of 106 patients who entered the study, 78 had assessments of psychiatric symptomatology and social adjustment both before treatment and after 4, 8 and 24 months. There was no significant difference in outcome between depressive, phobic, and anxiety neurosis, and no overall difference in response to treatment between the three types of care. Suicidal symptoms were significantly less common in out-patients. In many respects, neurotic disorder can be regarded as a single syndrome.

Considerable argument still occurs over the most appropriate treatment for the great range of neurotic disorders seen in clinical practice. Although there is good evidence that behaviour therapy (Marks, 1981), cognitive therapy (Beck *et al*, 1979), and drug treatment with tricyclic antidepressants and monoamine oxidase inhibitors (Rowan *et al*, 1982; Sheehan *et al*, 1980) are all effective treatments, there is no consensus on their relative value. Treatment is also governed by important practical considerations such as the availability of adequate time and personnel; for example, if psychotherapeutic procedures were preferred, they could not yet be used on a wide scale because of the cost involved in training extra personnel. However, the expansion of day hospital services over the past 30 years has offered an opportunity of treating patients with neurotic disorders more intensively than as out-patients, and also relatively cheaply. This has led to the growth of three classes of day patients: one consisting of relatively serious psychiatric illness that might otherwise need psychiatric in-patient care if the day hospital were not available (Hirsch *et al*, 1979; Dick *et al*, 1985); another with chronic disorders that come for support rather than an active treatment programme; and a third group of less seriously ill patients, frequently with neurotic disorders, who attend the day hospital for specific treatment, which is often psychotherapeutic (Gath *et al*, 1973).

We have presented the preliminary findings of a study of the efficacy of out-patient treatment for the three most common neurotic disorders – anxiety, phobic and depressive neurosis – compared with treatment in two day hospitals, one specialising in psychotherapeutic intervention and the other offering a range of treatments to patients with all types of psychiatric disorder (Tyrer & Remington, 1979). No important differences were found between the two types of care with respect to either symptomatic change or social adjustment, but patients in general were more satisfied with out-patient treatment than with day care. We report here further details of the outcome of these patients, with assessments made two years after initial treatment.

Method

The main part of the study was between March 1976 and November 1977. New patients referred to the out-patient clinics of four consultant psychiatrists and two academic consultants in Southampton were included if they were diagnosed as having anxiety, phobic, or depressive neurosis, using the terminology of ICD-8 (World Health Organization, 1967), had a disorder of intermediate severity so that attendance as a day patient or as an out-patient was equally feasible and acceptable to the patient, and were aged between 16 and 60. After initial assessment, the patients were allocated randomly to out-patient or day care. Those allocated to out-patient care continued to attend the clinics of the consultant team to whom they were originally referred. Of those patients allocated to day care, half were referred to a specialised day hospital that had a higher level of staffing (one professor, one lecturer, one senior house officer, one part-time psychologist, and three trained day nursing staff for a unit with six beds and up to ten day patients). This concentrated on psychotherapeutic management (including individual and group psychotherapy and psychodrama) and had a selection bias in favour of neurotic patients. The remaining patients were referred to a more typical day hospital which had a mixed therapeutic orientation and catered for a wider range of psychiatric disorder; the staffing of this comprised one consultant, one registrar, four trained nursing staff, and one part-time psychologist for a maximum of 40 patients.

Assessment of symptoms was made without knowledge of the patients' treatment and form of management. Ratings included a modified form of the Present State Examination (PSE) (Wing *et al*, 1974), in which cut-off instructions were ignored, all items referring to neurotic symptomatology scored, and additional items of anxious symptomatology (cardiovascular symptoms, respiratory symptoms, gastrointestinal symptoms and tremor) also included. The scoring of these items included both the conventional categorical rating of the PSE and scores on analogue scales, each of 100 mm. Social adjustment was assessed using the Social Functioning Schedule (Remington & Tyrer, 1979), in which function in 12 areas of activity is recorded on analogue scales. Both clinical status and social functioning were assessed before treatment and after four and eight months. A total of 106 patients were included in the study, of whom 89 completed treatment with these two assessments. No significant differences were found between the three forms of care for global symptomatology and social adjustment, but scores for individual symptoms and diagnostic groups were not analysed at that stage.

Because many of the patients were still handicapped by symptoms and were receiving care after eight months of treatment, and because there is evidence that the full effects of psychotherapy are not manifest for many months (Weissman *et al*, 1974), patients were followed up two years after their first assessment. All were contacted by letter, and assessments made at their home. If contact was not established, further enquiries were made to determine the patient's whereabouts and likely progress. Even if patients were not interviewed, further information was obtained for as many of them as possible, since the results of follow-up enquiries in neurotic disorder can be vitiated by lack of information on a significant proportion of patients, who often provide the most important information (Sims, 1973). Ratings of clinical state and social adjustment were made using the same instruments as in the earlier assessments, so that direct comparison could be made. Good inter-rater reliability had been established previously with the use of tape recorded interviews and consecutive assessments of patients, and the reliability of the analogue PSE ratings was shown to be at least as good as the conventional categorical scoring system (Remington *et al*, 1979).

Results

Patients

During the 21 months of recruitment, 264 patients were screened as possibly suitable for entry; 158 of these were excluded at initial interview (49 who could not attend or were considered not suitable for day hospital treatment, 20 whose disorders were considered too minor, 17 for whom the diagnosis was not that of depressive, phobic, or anxiety neurosis, 9 who were admitted to hospital immediately, 3 for other reasons, 26 who did not attend, and 34 for whom no reason was given by the doctor for their exclusion). Of the 106 patients included, 78 (74%) were seen at four months, eight months, and two years. The reasons for failure to complete assessments are given in Table I. No patients were in-patients at the time of follow-up, and all patients who refused interview had no current contact with the psychiatric services. There was a similar drop-out rate in each of the treatment and diagnostic groups. Of the 78 patients completing assessment, 51 had an ICD-8 diagnosis of depressive neurosis, 16 a diagnosis of phobic neurosis, and 11 a diagnosis of anxiety neurosis.

Differences between treatments

The clinical and social adjustment ratings showed roughly normal distributions, and so differences between groups over time were subjected to parametric analyses, primarily of covariance. During the two years of follow-up it was considered unethical to confine patients' treatment to either day hospital or out-patient settings, and clinical management was left to the discretion of the individual clinician concerned. In the first eight months of treatment a detailed record was kept of all treatment given; this has been

3. Not included in full PSE.

*Improvement significantly better than for other groups, $P < 0.05$; **$P < 0.001$.

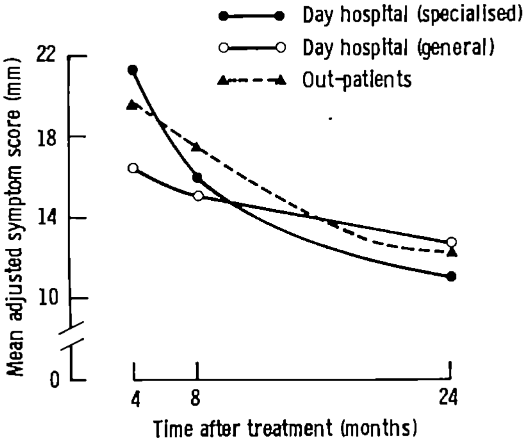

FIG. 1 Mean adjusted PSE scores of each treatment group

summarised by Tyrer & Remington (1979). Predictably, patients attending the out-patient clinic had a significantly shorter duration of treatment, a smaller number of attendances, and less group and occupational therapy. Between the eight-month and two-year follow-ups, only three patients originally allocated to the out-patient group had been referred to a day hospital facility, and in all three cases this was for less than two months. A much larger proportion (76%) of patients originally treated at a day hospital had received some form of out-patient care in this time. The data after two years therefore came from an out-patient group that had received out-patient care almost universally throughout this period and a day patient group who had received a mixture of day hospital and out-patient care. A small number in each group had also received in-patient care (six in the day hospital and four in the out-patient groups).

The mean adjusted symptom scores on the analogue forms of the PSE showed no significant differences between the three types of treatment. Although patients in the general day hospital showed more rapid early improvement, this was not maintained, and the patients at the specialised day hospital showed most of their improvement later in the course of treatment (Fig. 1). These differences, however, fell short of significance ($F = 1.2$). Similar findings were shown with the mean adjusted social function score, except that the amount of improvement shown over the course of the two years was less than that for symptoms (Fig. 2).

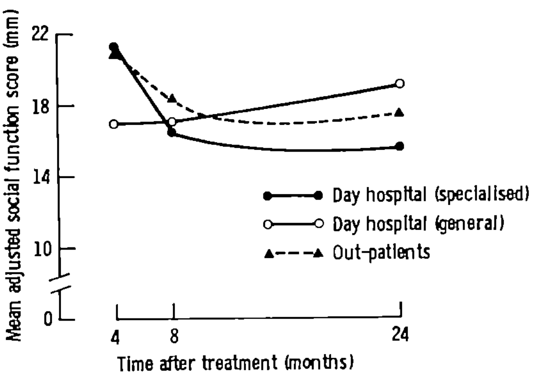

FIG. 2 Mean adjusted social function scores of each treatment group

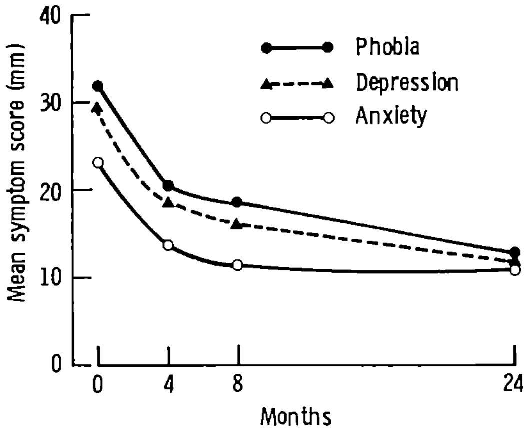

FIG. 3 Mean PSE scores of each diagnosis group

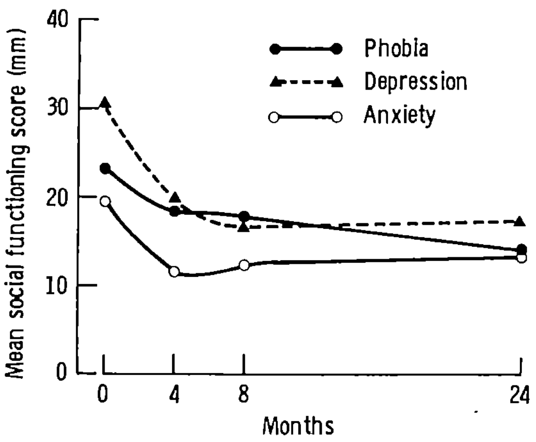

FIG. 4 Mean social function scores of each diagnosis group

The 30 symptoms constituting the mean symptom score were analysed separately; the results for these showing significant differences are given in Table II. After four months the symptoms of worrying, anxious foreboding, subjectively ineffective thinking, and poor concentration were significantly better in the general day hospital group, while one symptom, hypochondriasis, improved more in the specialised day hospital group. After eight months, ratings of hopelessness were significantly better in the specialised day hospital group, as were the symptoms of panic attacks, tremor, and loss of interest in the same group after two years. For all these items significant superiority was only shown at the 5% level; in view of the large number of comparisons, several of these could have occurred by chance. The only highly significant difference was for ratings of suicidal plans or acts, where the out-patient group had significantly lower scores than both day hospital groups at follow up ($P < 0.001$).

Differences between diagnostic groups

There was a similar improvement in the symptom scores of all three diagnostic groups (Fig. 3). Phobic patients had the most symptoms at the beginning of treatment, but this was not significantly different from the other two groups. By the time of follow-up, all three groups had similar mean symptom scores. a similar pattern was shown for ratings of mean social function (Fig. 4). At the beginning of treatment, phobic patients had significantly worse social functioning than anxious ones ($F=4.2$; d.f. 2, 75; $P < 0.02$), but at follow-up these differences became less and were not significant. After two years, the mean social functioning was similar in all three groups.

Discussion

The results show that there is no appreciable difference between the short or medium-term outcome of neurotic patients treated initially at out-patient clinics or at day hospitals. Thus, it is fair to conclude that a day hospital facility for the treatment of neurotic disorders alone is not a necessary part of a psychiatric service. However, as the selection criteria for the study ensured that the patients treated had an intermediate degree of handicap which allowed out-patient and day hospital care to be practical alternatives, it would be wrong to generalise too widely from the findings. Day hospitals are now used increasingly as an alternative to hospital admission, and the degree of handicap appropriate to this use was excluded from our study.

Such differences as were shown favoured each type of care, but at different times of follow-up. The general day hospital had its greatest therapeutic impact early on in treatment, and tended to show a better outcome than the other facilities after four months. As the general day hospital provided a full range of treatments, particularly those directed to symptomatic improvement, this result is not surprising. What is unexpected is the failure of patients to maintain their improvement over the two-year period of follow-up, to the extent that after two years this group showed greater social dysfunction than after four months. It is possible that the availability of all psychiatric treatments in a supportive setting might prevent investigation of the underlying causes of poor social functioning and also lead to a degree of dependence on the day hospital.

The specialised day hospital showed an opposite trend, with relatively poor improvement after four months and steadily greater improvement thereafter, so that after two years this group had the best social adjustment and symptomatic outcome (Figs 1 and 2). This is in keeping with evidence that the beneficial effects of dynamic psychotherapy often take many months to become established fully, and that a period of increased distress and symptomatology often precedes the improvement (Weissman *et al*, 1974).

The out-patients occupied an intermediate position in outcome, and showed only one important difference from the two day hospitals groups – on ratings for suicidal behaviour after two years ($P < 0.001$). It may also be relevant that two patients committed suicide in the day hospital groups and one was killed by his wife during the period of follow-up; she was subsequently cleared of murder and convicted of manslaughter because of his extreme provocation. This finding is also consistent with evidence of greater distress during the initial phase of psychotherapy, and suggests that patients thought to be at risk of suicide should be assessed carefully before any form of psychotherapy is considered.

Taking the relative costs of out-patient and day patient care into consideration, the findings indicate that out-patient treatment is a cheap and effective form of management, but could be improved further by developing a greater range of treatments, including psychotherapy. Day hospital care is also probably effective, but as it was combined with out-patient care for much of the follow-up period it is difficult to establish its main contribution to outcome. The future development of psychiatric day hospitals cannot be planned clearly because of equivocal findings concerning their value (Vaughan, 1985), but the results of this study counsel caution in developing specific facilities for treating neurotic disorder.

Economic considerations also are important in preferring different types of psychiatric service. Day hospital treatment is considerably cheaper than in-patient care (Dick *et al*, 1985), and when all the administrative costs of running a day hospital are taken into account, out-patient care is cheaper. One advantage of the day hospital is that less expensive medical time is spent with the patient. Analysis of the length of time spent in treatment by each patient after eight months, however, showed that out-patients averaged four hours of treatment, whereas the average duration of therapy of each day patient was 103 hours in the general day hospital and 73½ hours in the specialised day hospital (Tyrer & Remington, 1979). These figures suggest that although the out-patient contact may be more expensive per unit of time, it is considerably more economical over a course of treatment.

The outcome of the three diagnostic groups also showed no important differences in the two years of follow-up. Anxious patients had significantly better social functioning and relatively fewer symptoms than phobic and depressed patients before treatment (Figs 3 and 4), but this difference disappeared over time. This agrees with other evidence that anxious patients have relatively good social functioning compared with other diagnostic groups (Casey *et al*, 1985), and that phobic and depressed patients differ from anxious ones in having specific symptoms together with those of anxiety, rather than having qualitatively distinct disorders (Prusoff & Klerman, 1974). In the course of follow-up the symptoms and social function scores of each of the three groups converged, so that after two years the mean scores were virtually identical. Thus, the distinguishing features that helped to make the diagnosis before treatment did not remain consistent over time. Our findings confirm other evidence that the temporal reliability of neurotic disorders is low (Kendell, 1974), and that for most purposes neurotic patients can be treated as a relatively homogeneous group, those having higher PSE scores at initial assessment usually being classed as having phobic or depressive disorders, and those with lower scores being diagnosed as having anxiety neurosis.

The evidence of this study, together with the arbitrary nature of current classification of neurotic disorder (Tyrer, 1984), suggests that many of the diagnostic subdivisions of neurosis are of limited clinical relevance (Tyrer, 1986) and that many cases could be classified as a single disorder, the general neurotic syndrome, which runs a prolonged course with variation in the predominance of different neurotic symptoms over time (Tyrer, 1985). The difference in outcome between depressive and anxiety neurotic disorders shown by some workers is not as contradictory as it first appears; e.g. Schapira *et al* (1972) found a greater percentage improvement in depressed patients compared with those with anxiety states over a period of four years after first assessment. Our findings are similar, except that we make the important additional point that patients with predominant anxiety are at a relatively better phase in the course of the general neurotic syndrome, and so are less likely to improve than patients with many more symptoms, including depression. Thus each patient can have predominantly depressive, phobic, and anxiety symptoms at different times; the labelling of the neurosis through its dominant current symptomatology is not such an important distinguishing feature as conventional classification would have us believe.

More evidence is needed, using DSM-III (American Psychiatric Association, 1980) and other systems of classification more appropriate to research studies than ICD-8, before this conclusion can be accepted. Nevertheless, it suggests that other research workers should take into account temporal variations in neurotic symptomatology, as well as those dominating at the time of presentation, before attaching firm diagnostic labels.

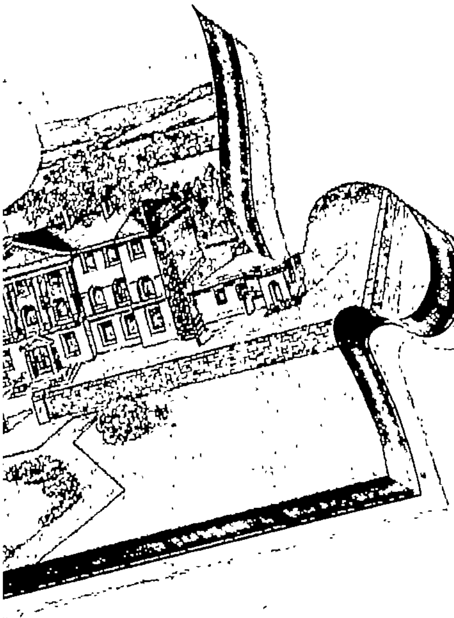
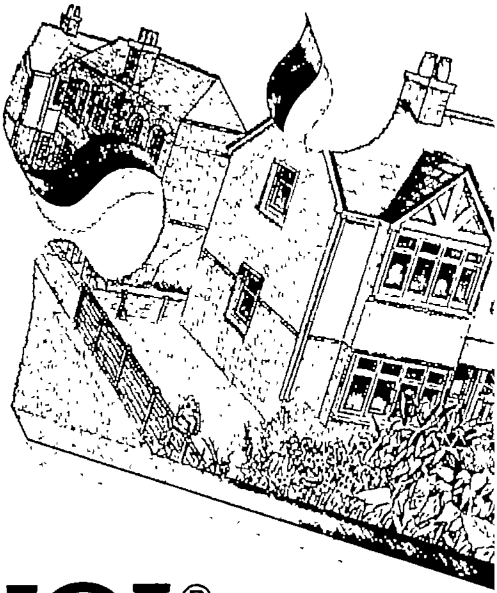
From Clinic to Community





CLOPIXOL®

zuclopenthixol dihydrochloride/decanoate

TABLETS • INJECTION • CONC INJECTION

PRESCRIBING INFORMATION

CLOPIXOL TABLETS contain zuclopenthixol dihydrochloride.
Indications Psychoses.
Dosage and Administration The usual initial dose is 20-30mg/day, increasing as necessary to a maximum of 150mg/day, in divided doses. The usual maintenance dose in chronic schizophrenia is 20-50mg/day in divided doses.- Not recommended for children.
Side-effects Extrapyramidal side-effects may occur and sometimes may require control by anti-Parkinson drugs.
Contraindications Acute alcohol, barbiturate or opiate poisoning. Intolerence to other neuroleptics. Pregnancy (relative). Use with caution in patients with Parkinsonism, severe arteriosclerosis, senile confusional states; serious renal, hepatic or cardiovascular disease.
Overdosage Overdosage should be treated by gastric lavage.
Package Quantities and NHS Price (correct at time of printing) Bottles of 100 Clopixol Tablets 2mg £3.05, bottles of 100 Clopixol Tablets 10mg £7.50, bottles of 100 Clopixol Tablets 25mg £15.00.
PL Nos 0458/0027,0028,0029 PA Nos 115/5/3,4,6.

CLOPIXOL INJECTION & CLOPIXOL CONC. INJECTION contain zuclopenthixol decanoate 200mg/ml and 500mg/ml respectively in thin vegetable oil.
Indications Psychoses, especially schizophrenia.
Dosage and Administration 200-500mg every 2-4 weeks by deep intramuscular injection.
Not recommended for children.
Side-effects Early (frequent) and late (rare) dyskinesias. Extrapyramidal effects sometimes require dose reduction or anti-Parkinson treatment.
Contraindications Comatose states.
Precautions Caution in patients with advanced renal, hepatic, or cardiovascular disease, Parkinson's disease, pregnancy, car driving or machine operation.
Further Information Overdosage should be treated by (a) anticholinergic anti-Parkinson drugs if extrapyramidal symptoms occur. (b) By sedation (with benzodiazepines) in the unlikely event of agitation or excitement. (c) By noradrenaline in saline intravenous drip if the patient is shocked
Package Quantities & NHS Price (correct at time of printing) 10 x 200mg (1ml) ampoules £30.14, 1 x 200mg (10ml) vial £28.63, 5 x 500mg (1ml) ampoules £36.23.
PL Nos 0458/0017,0041. PA Nos 115/5/1,5,7

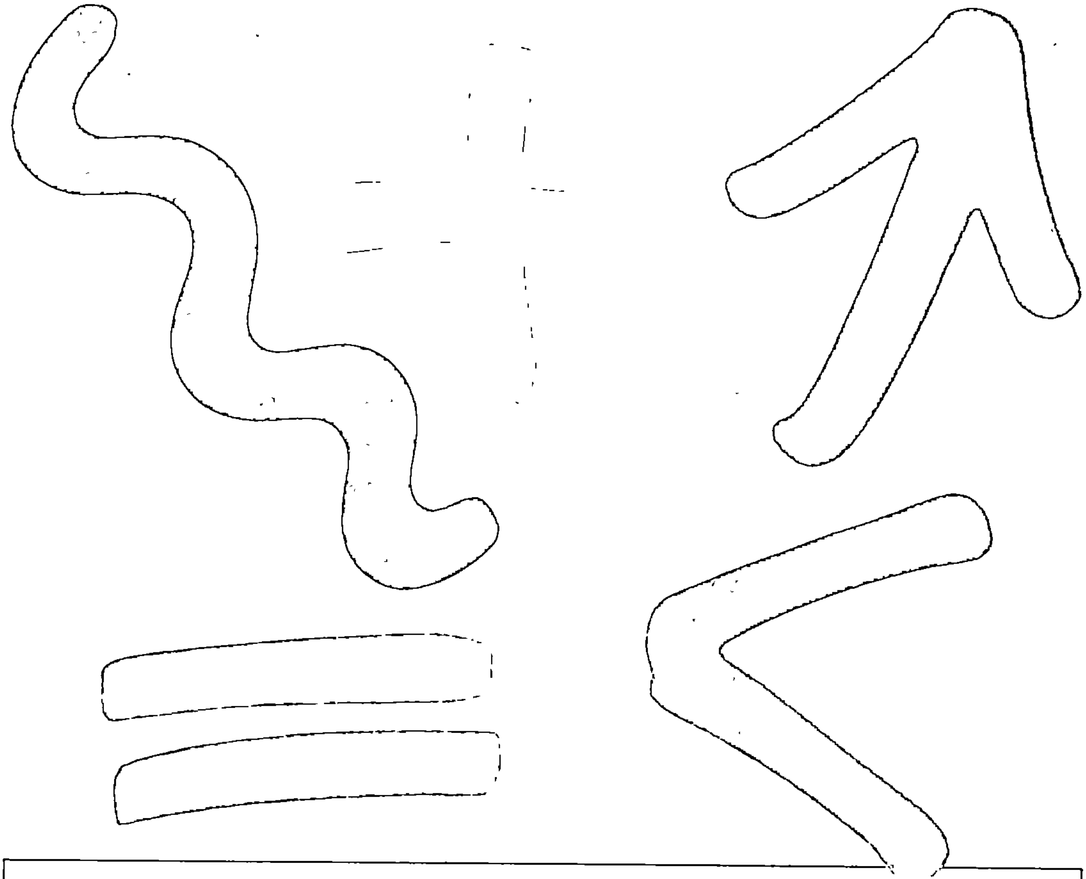
THE DEPIXOL

cis(Z)-flupenthixol decanoate



DIFFERENCE

≡ Proven antipsychotic effect (1-7)

↑ Restores mood (1-3)

∿ Dosage flexibility

< Cost-effective therapy (8)

PRESCRIBING INFORMATION

Depixol Injection and Depixol-Conc. Injection contain cis(Z)-flupenthixol decanoate, 20mg per ml and 100mg per ml respectively, in thin vegetable oil
Indications Psychoses, especially schizophrenia, particularly where there are associated features of withdrawal, inertia or apathy
Dosage and Administration By deep intramuscular injection, 1-2ml every 2-4 weeks, to a maximum of 400 mg weekly. Children Not recommended for children
Side Effects Early (frequent) and late (rare) dyskinesias. Extrapyramidal effects sometimes require dose reduction or anti-Parkinson drug treatment.
Contra-indications Not recommended for overactive patients, or for those with Parkinsonism, severe arteriosclerosis, senile confusional, or advanced renal, hepatic, or cardiovascular disease, intolerance to other neuroleptics, pregnancy

Further Information Overdosage should be treated; (a) by anticholinergic anti-Parkinson drugs if extrapyramidal symptoms occur, (b) by sedation (with benzodiazepines) in the unlikely event of agitation or excitement, (c) by noradrenaline in saline intravenous drip if the patient is shocked.
Package Quantities & Basic NHS Prices Boxes of 10 x 20mg (1ml) £15 53, 10 x 40mg (2ml) £25 99, 10 x 100mg (1ml) ampoules £59 53, 5 x 20mg and 5 x 40mg syringes £8 51 and £13 74, 1 x 200mg (10ml) and 1 x 500mg (5ml) vials £14 74 and £28.27.
PL Nos 0458/0007/0015 PA Nos 115/1/1,2,3,5,6,7,8.

Does Violence Have Cognitive Correlates?

G. ROBERTSON, P. J. TAYLOR and J. C. GUNN

The relationship between cognitive function and violence in 76 remanded prisoners, without formal psychiatric illness, was investigated. The violent group tended to be of slightly lower general ability than the non-violent group, but not abnormally so in relation to the general population; no relationship was found between specific patterns of cognitive functioning and violence. The violent group reported significantly higher levels of neurotic symptoms than the non-violent group, and were more socially deviant. To a small extent, general intelligence (reasoning ability), in interaction with many other factors, may be related to a propensity for violent behaviour, but no particular aspect of cortical functioning seems to be related to violence.

The search for features of brain structure and function which underlie behaviour is inevitable. While social and other environmental influences are undeniably important in formulating behaviour, neuronal activity is the final common pathway for perception, judgement, and action.

In the field of violence and cerebral pathology there has been an almost exclusive preoccupation with the link between cerebral dysrhythmias and aggression, perhaps principally because of the episodic nature of most violence; Kligman & Goldberg's critical review (1975) still stands as one of the most important contributions. Little can be inferred from most of the data, since terminology, whether covering behaviour or electroencephalogram (EEG) findings, is vague and over-inclusive. Double-blind studies, despite being easily conducted in this field, are almost non-existent, although Fenton *et al* (1974) reported one in a series of special hospital patients which showed no more than a slight trend for patients with posterior temporal slow wave anomalies to be more violent than those with normal EEGs. The organic contribution to violence is even more difficult to interpret from other neurophysiological studies, since most refer to 'psychopaths', the definition of which is often based on subjective criteria and leaves the level of violence unclear. Howard (1984) attempted to tighten the criteria, but even so, the nature and degree of violence within the population must generally be inferred from such data. Certainly the relationship between violent behaviour, personality type, and EEG abnormality is extremely complex.

Neuropsychological testing has been, perhaps, the greatest growth area. Spellacy (1978) reported that he could classify subjects as violent or non-violent with a 95% accuracy on a neuropsychological test battery; his violent sample was of significantly lower general intelligence than his non-violent group. Krynicki (1978) also used a neuropsychological test battery to compare repetitively assaultive adolescents with non-violent delinquents and an age-matched group with organic brain disorder. The violent and the organic groups were almost indistinguishable, with a tendency for left-sided disturbance to predominate in the violent group.

The remaining literature, in common with the neurophysiological material, focuses on 'psychopathy' – defined on various scales – with the recurring difficulty that raw data on violence are not reported. In relation to psychopaths, Flor-Henry (1973) has asserted that this condition is associated with left-hemisphere pathology, although his early data was from a small series of seven 'homicidal psychopaths', six of whom, on neuropsychological testing, showed disorder in the anterior limbic region, five of them bilaterally but with a stronger tendency to right-sided disorder. Yeudall *et al* (1981), from the same department, reported that 70% of aggressive psychopaths had abnormal neuropsychological profiles, indicating dysfunction localised to the frontal and temporal regions of the brain. Fedora & Fedora (1983) added that the psychopaths differed from controls only on neuropsychological variables considered to be left hemisphere, and on anterior/impulsivity markers. Gorenstein (1982) reported a relationship between frontal lobe deficits and psychopathy, but his findings have been questioned by Hare (1984), who stressed the need for more adequate definitions of what constitutes psychopathy and for caution in the interpretation of studies involving cognitive tests. In so far as localisation of function can be inferred by the studies described, evidence does favour the association of disruption of left-hemisphere function with violence.

The purpose of the study reported here was to determine, using a specially devised psychological test battery, whether any cognitive differences could be found between men who had shown a predisposition to violence and those who had not. Earlier work by Taylor *et al* (1982) had indicated that, in terms of handedness, non-violent men and men who had been violent on one occasion only could be distinguished from those with a more substantial record of violent behaviour. The criterion used for inclusion in the violent group in the present study was that the man had a long and significant record of violence. The relationship between violence and cognition was investigated in a mentally ill population and for men regarded as non-ill. This paper concerns the latter population; a report on the former is in preparation.

Method

Subjects

Between April and December 1982, 167 men, 76 of whom were not suffering from any formal mental illness, were interviewed and tested. All the non-ill men were tested and interviewed in Brixton prison, which was chosen because it holds men during the period before trial, thus providing a large turnover of potential subjects. The range of 'violence' represented in this population was enormous both in terms of severity and frequency.

Both violent and non-violent non-ill groups were selected, in some measure, by exclusion criteria. Men with a history of any of the following were excluded: schizophrenia, affective psychosis, epilepsy, brain injury, other known or suspected organic illness, or dependence on drugs or alcohol. Selection was carried out on the basis of age compatibility with the ill group, and men were selected for the violent, non-ill subgroup if the offence with which they were charged was of serious personal violence and if their records also indicated that they had been convicted of violent offences in the past.

Each man selected was called to the hospital wing and asked if he would take part in the study. A brief explanation of its purpose was provided, and the confidential and voluntary nature of the study stressed. Most men agreed to participate, but a number who had been chosen on the basis of their violent record alone refused; these tended to be those with extremely long criminal records of extensive violence.

Procedure

Having agreed to take part, each man was interviewed and assessed on a battery of cognitive tests developed for this project. Interviews took 20–40 minutes to complete, and covered criminal and psychiatric history, basic demographic material such as education, marital status, and employment, and the circumstances surrounding the man's arrest and detention (subjects were prepared to take on trust assurances of confidentiality, and spoke freely about the latter despite the fact that some were going to plead not guilty). Cognitive testing followed the interview, and took 1–1½ hours. Each man was then asked to complete a present state symptom checklist – the SCL-90 (Derogatis *et al,* 1973) – which allowed him to describe his subjective experience of psychopathology, while the interviewer completed the observer ratings of the Comprehensive Psychopathological Rating Scale (CPRS) (Asberg *et al,* 1978) for an objective description.

Tests used

Wechsler Adult Intelligence Scale

The Wechsler Adult Intelligence Scale (WAIS) (Wechsler, 1955) was used to measure verbal IQ (prorated from vocabulary, similarities, and digit span sub-scales) and performance IQ (prorated from picture completion, block design, and picture arrangement sub-scales).

Verbal fluency

A decrease in verbal fluency has been reported as being associated with frontal brain damage (Benton, 1968). In the present study, verbal fluency was measured on four subtests, all of which required the production of words for one minute each. The first part – 'free association' – allowed the production of any word (except plurals, tenses, etc); the second required the person to name as many animals as he could think of in the space of a minute; and the third and fourth parts required the production of words beginning with the letters S and F respectively. These results are reported as the total number of legitimate words recorded in each one-minute period.

Visual retention test

Brain-damaged patients with lesions of the right hemisphere have been reported as deficient in their recognition of unfamiliar faces (Warrington & James, 1967). This has been used as the basis of three sub-tests, grouped here as the 'visual retention test'; each was designed to reflect hemispheric function, other factors being held constant. In each sub-test 20 pictures were shown, individually, for approximately three seconds each. Immediately afterwards the same 20 pictures were presented, this time each one being set alongside a similar picture. The task was to identify the picture he had seen initially. The score was taken as the total number of wrong answers out of 20.

The first sub-test ('simple verbal') consisted of single items which were deemed to be easily remembered in a verbal fashion, e.g. a car or a packet of cigarettes. The second ('mixed function') consisted of items which were much more complicated or which required much greater discrimination for correct identification at second presentation than those in the first sub-test. The third subtest ('faces') consisted of 20 pictures of unfamiliar faces.

The theory underlining the design of the tests was that they should reflect a shift from non-verbal (right hemisphere) function through to purely verbal (left hemisphere) function.

Visual recognition test

This was adapted from a procedure used with a brain-damaged population (Faglioni *et al*, 1969). The adaptations reflect our interest in pattern of response. In each of the four sub-tests the subject was asked to identify a letter or figure at the top of a column and then match that letter or figure with one of a series of eight or five alternatives presented below it. The time taken to identify the correct figure was recorded, as was the number of errors made; the cumulative time taken for the items in each sub-test was calculated, and is used to represent the test result. Sub-tests were designed to reflect a shift in function from 'pure' verbal function (sub-test 1) through to 'pure' spatial organisation (sub-test 4). They have been titled: (1) 'alphabet'; (2) 'embedded letter'; (3) 'broken letter'; and (4) 'broken figure'.

In addition to these tests, reading age was assessed, using the Schonell Graded Word Reading Test (Schonell & Schonell, 1965), and handedness preference, using the Annett Handedness Preference Scale (Annett, 1970).

Results

The division into violent and non-violent subgroups was made on the basis of the scores obtained by men on two violence rating scales (Gunn & Robertson, 1976). The first of these five-point scales was concerned with the present offence, and the second with the man's record of violence; details are given in Appendix 1. Because of the manner of selection of the violent group, the previous and present violence scales were highly correlated in the non-ill population ($r=0.72$), and it was decided that the best distribution of the criterion variable would be obtained by totalling these scales. Those men with a total score of 0–3 were placed in the non-violent group, and those with scores of 4–8 in the violent category. Only one man had a score of 4, and the criterion cut-off point is considered adequate.

The raw scores of the cognitive test data were transformed to z standard scores, with a mean of 0 and a standard deviation of 1; this information is presented in the form of cognitive profiles in Fig. 1. The most striking feature of the two profiles is their similarity in pattern. The two groups were not found to produce statistically different distributions on any of the sub-tests used, although the violent group produced inferior scores on every sub-test bar one (the similarities sub-test of the WAIS). The two groups were similarly distributed with regard to age, the mean for the non-violent group being 34.4 (s.d. = 8.94 years) and that for the violent group 31.4 (s.d. = 8.84 years), and with regard to the assessment made of their reading ability ($t=0.24$, $P<0.81$).

Although not different on any single cognitive test in the battery, the two groups could be distinguished from one another fairly well in terms of overall functioning. Evidence of this was provided by a classification of cases into violent and non-violent groups on the basis of scores determined from a discriminant function analysis. Four men were excluded from the analysis because of missing data. The overall rate of correct identification was 75%. Of the 34 men in the non-violent group, 24 (71%) were correctly classified on the basis of their scores on the function derived from the analysis and 10 (29%) were misclassified. Of the 38 in the violent sample, 30 (79%) were correctly grouped and 8 (21%) incorrectly categorised on the basis of their discriminant function scores. The nature of the derived function, as assessed by the discriminant function coefficients of the sub-test, appears to be non-specific as regards hemispheric function and biased towards higher reasoning ability. Irrespective of sign, the sub-tests with the highest loadings were: similarities sub-test (WAIS), 0.72; production of words beginning with the letter S, 0.71; performance on the broken figure and embedded letter sub-tests in the visual recognition group, 0.58 and 0.51 respectively; and scores on the block design sub-test (WAIS), 0.48.

The two groups were also found to differ on a number of variables related to social functioning (Table I). Although similar proportions of men in both groups had married, the violent group contained significantly more men who were either separated or divorced. Long-term unemployment was also more frequent among the violent men, all of whom had had a previous criminal record (compared with 80% of the non-violent sample), and significantly more violent men had juvenile convictions on their records.

Table II shows the psychiatric variables on which the two groups differed. There were indications of greater instability in the violent sample; for example, a greater proportion of them had previously received psychiatric treatment, and more were receiving medication at the time of interview. Despite large within-group variability, the two groups were also distinguished with regard to the reporting of neurotic symptoms on the SCL-90 self-report schedule. In particular, the violent group tended to report a greater awareness of paranoid feelings, although men in the violent group may in fact have had real enemies in the criminal underworld who wished them harm. The violent group also proved to be 'deviant' in terms of their previous drinking and other drug-taking behaviour. The two groups did not differ when rated by the interviewer on the observed psychopathology section of the CPRS rating scale; however, such scales are relatively insensitive, particularly when used on subjects without formal psychiatric illness.

Discussion

In regard to the pattern of their cognitive profiles, the violent men in this study did not differ from non-violent men. A discriminant function analysis produced a good degree of separation between the groups, and this has been interpreted as reflecting relative inferiority among the violent group in terms of general ability. It may be argued on the basis of the discriminant analysis (e.g. the high loading of the similarities sub-tests and of one of the verbal fluency

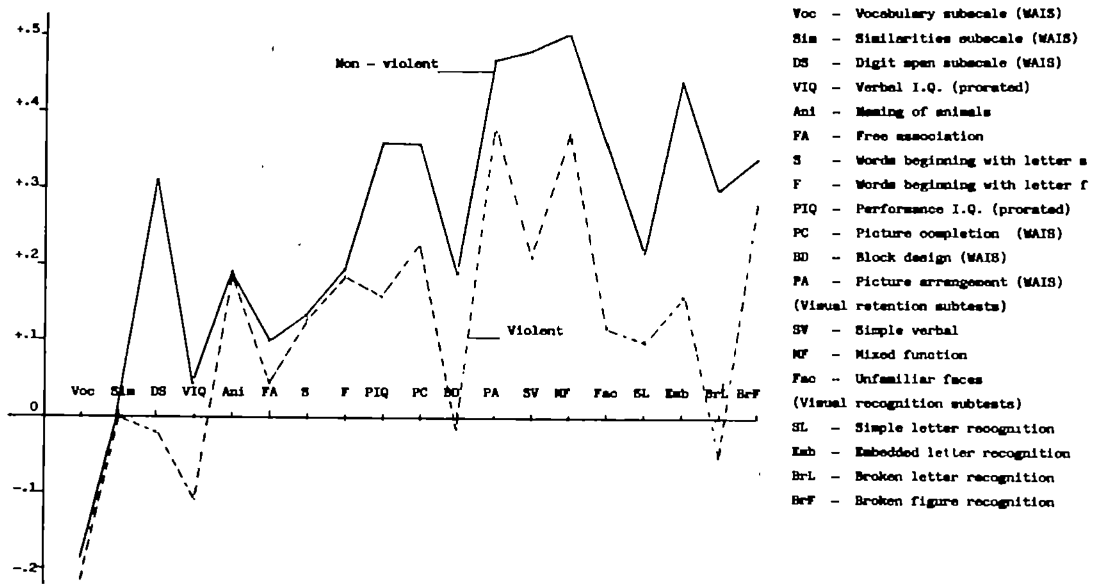

FIG. 1 Comparison between violent and non-violent groups (all scores have been subjected to a Z transformation, so that mean = 0 and s.d. = 1).

TABLE I

Comparison of violent and non-violent, non-ill groups on social and criminal variables

	Violent (n = 35)		*Non-violent (n = 41)*		*t*	*P*
	Mean	*s.d.*	*Mean*	*s.d.*		
Drink rating (historical)	1.68	1.15	0.79	0.85	3.92	0.001
Drugs rating (historical)	0.74	0.95	0.29	0.56	2.46	0.017
Age at first offence	15.03	3.35	22.85	11.20	4.21	0.001
Number of juvenile offences	3.28	4.64	0.88	1.74	2.90	0.006
Total court appearances	12.88	8.42	5.48	5.29	4.44	0.001
Previous prison sentences	4.71	4.84	1.44	2.20	3.69	0.001
	Yes	*No*	*Yes*	*No*	χ^2	*P*
Whether separated or divorced	13	22	6	35	3.97	0.05
Unemployed more than 6 months	20	15	12	29	6.02	0.02

sub-tests) that frontal lobe functioning is particularly impaired in the violent group. However, such an interpretation would be incorrect, as it was on the similarities sub-test that the violent group produced the higher mean score. Furthermore, a higher proportion of men in the violent group were receiving medication (Table I); those who were on medication were significantly inferior on the similarities sub-test to those who were not. The mean score for men not on medication was 11.03 (s.d. = 1.63), compared with a mean score of 9.16 (s.d. = 1.60) for those receiving drugs ($t = 2.55$, $P < 0.015$).

Rather than implicating a particular area of the brain, the present results are better accounted for in terms of a 'general cortical function' or 'general intelligence' model. The overall distribution of the prorated intelligence quotients for the violent group, though slightly inferior to that of the non-violent

TABLE II

Comparison of violent and non-violent, non-ill groups on psychiatric variables

	Violent ($n=35$) Mean	s.d.	Non-violent ($n=41$) Mean	s.d.	t	P
SCL-90 total score	85.48	62.76	56.75	53.96	2.12	0.038

Any previous psychiatric contact	11	24	5	36	3.12	0.07
Receiving any medication	6	29	1	40	3.28	0.07

sample, was well within normal limits, 59% of the group producing full scale IQ scores of between 90 and 110.

How do these results compare with earlier studies? Yeudall *et al* (1981) reported that "70% of aggressive psychopaths were found to have abnormal (neuropsychological) profiles indicating dysfunction localised to the frontal and temporal regions of the brain". This 'localisation', however, may reflect the nature of the tests used; indeed, given that most 'higher order' cognitive activity probably takes place in the temporal and frontal lobes, to report the same is to do no more than to report general impairment of function. In general, tests which purport to measure functioning outwith these areas are described and used as measures of gross impairment, rather than in terms of normal distribution statistics. Furthermore, the method of classifying what constituted abnormality was different. We considered group scores, whereas in Yeudall *et al*'s series individual profiles were rated for evidence of abnormality. Unfortunately, neither the criteria used to define that term nor the nature of the control group of normal subjects used in that work were made explicit.

The study by Spellacy (1978) resembles the present work in that it compared groups of violent and non-violent prisoners; he concluded that his subjects "could be classified correctly as violent or non-violent with 95% accuracy by use of (his) neuropsychological battery alone". The principal difference between his violent and non-violent subjects was the significantly lower general intelligence of his violent sample. He reported verbal, performance, and full-scale IQ discrepancies on the WAIS in the region of 12–14 points; these differences were all statistically significant at the one in a thousand level, and are thus among the most discriminatory items in his test battery. However, there was much greater overlap in the IQ distributions of the two groups in the present study, and it must be assumed that the reason for this marked difference in test results is due to sampling differences. In Spellacy's series "the violent group was defined by an arrest record that contained at least two assault charges... and a demonstrated history of unpredictable aggressive behaviour". The assault charges could range from indecent assault to murder, and it is possible that this fairly broad definition biased the violent sample in the direction of minor assaultative violence and poor general intelligence – a bias not so apparent if the violent group is selected using more serious violence as a criterion.

This disagreement is an important one, in that earlier results clearly suggested that brain pathology, as measured by cognitive tests, is related to criminal aggression to a degree which merited further study. In contrast, the present work suggests that general ability may be related to a predisposition to violent behaviour, but to a more modest degree than that indicated by earlier studies, and that considerable overlap exists between violent and non-violent groups. No pattern emerged to implicate either hemisphere in relation to a history of violent behaviour.

Acknowledgements

We are grateful to the men who agreed to take part in this study and to the authorities of Brixton Prison Hospital Wing, and to Dr Maria Wyke and Mrs Maureen Bartholomew. The work was supported throughout by a grant from the Medical Research Council.

Appendix

iolence rating for present offence (abbreviated)

0. Completely non-violent.
1. Minimal violence (e.g. verbally aggressive, shouting or gesturing, even if this was not obviously directed at others).
2. Moderate violence (e.g. attack on a person resulting in no serious injury, fighting or brawling, or damage to property when this was the main intent).
3. Moderately severe violence (e.g. attack which resulted in serious injury but not detention in hospital for more than 24 hours, or damage to property which was extensive or which could have resulted in threat to life.
4. Severe violence (victim died or life and health seriously endangered).

Violence rating scale – overall record

0. Never been convicted of violence – never gets into fights.
1. Some evidence of violence (occasional fights but no convictions).
2. One or two convictions for minor assaults or damage to property.
3. Three or more convictions for violence, but none serious in the sense of '4' below.
4. One or more severely violent episode in which someone's life or health has been seriously endangered.

Cerebral and Brain Stem Changes After ECT Revealed by Nuclear Magnetic Resonance Imaging

A. J. MANDER, A. WHITFIELD, D. M. KEAN, M. A. SMITH, R. H. B. DOUGLAS and R. E. KENDELL

Nuclear magnetic resonance images of the brain were obtained in fourteen patients with major depression during a course of ECT. The T_1 relaxation time rose immediately after the fit, reaching a maximum 4–6 h later. The T_1 values then returned to their original level; no long-term increase occurred over the course of treatment. These results are consistent with an extensive but temporary breakdown of the blood-brain barrier during ECT.

Nuclear magnetic resonance (NMR) is a long established technique in physics and chemistry, but relatively new in medicine. Nuclei in a constant magnetic field can be made to resonate by the application of an oscillating magnetic field in the radiofrequency range. As the resonance decays to zero the radiofrequency radiation emitted by the nuclei can be detected; this is the basis of the NMR signal. The time taken for the nuclei to return to their original equilibrium position is the spin lattice relaxation time, T_1.

In medical NMR imaging, the signal is usually obtained from hydrogen nuclei (protons) within the body. Since most biological systems consist of 70–90% water, it is these water protons that cause the major component of the NMR signal. Solid tissues have short T_1 values, while relatively fluid tissues have longer ones. The T_1 of grey matter is significantly longer than that of white matter because of their different fat:water ratios. T_1 times can be altered by changes in the ratio of 'free' to 'bound' water in a tissue (Mathur De Vre, 1984) or in its total water content (MacDonald *et al*, 1985). NMR is therefore a useful tool for investigating possible changes in the brain during a course of ECT, particularly as there is no ethical objection to scanning patients repeatedly. Information obtained in this way about changes in the brain induced by ECT may also shed light on the intracerebral changes occurring after spontaneous epiletic fits.

Method

Eleven patients (4 male, 7 female, mean age 49.6 years) had an NMR scan before and after the administration of the first treatment (scans 1 and 2) and again before and after a later treatment (scans 3 and 4) of a course of ECT. A further three patients (all female, mean age 40.3 years) had a scan before and after their last treatment and then six further scans during the 6 h following the treatment. One of these had a final scan after 25 h. Of the total group of fourteen patients, eleven had bilateral and three had unilateral electrode placings; all of them satisfied Research Diagnostic Criteria for a major depressive episode (Spitzer *et al*, 1978). Patients were excluded if there was a history of serious head injury, brain damage, alcohol abuse or previous radiological abnormality. None had received ECT in the previous 6 months. A standard anaesthetic procedure was used: methohexitone (60–100 mg) and suxamethonium (30–80 mg). Four patients also received diazepam (2.5–10 mg i.v.) before scan 2. The treatment was delivered using an Ectron CC–100 machine, except in one case where a Mecta machine was used. The post-ECT scan was performed as soon as possible after the patient had recovered from the effects of the anaesthetic.

An M&D Technology Ltd 0.08 T resistive magnetic resonance imaging system was used. For each scan, calculated T_1 images were obtained in three planes: a transverse section 10 mm above the maximum diameter of the lateral ventricles, a midline sagittal section of the brain stem, and a coronal section through the parietal and temporal lobes. All sections were 12 mm thick, and the pixel size was 2 mm^2. Measurement of mean T_1 of the entire area of the transverse section (the grey and white matter together but excluding the cerebrospinal fluid (CSF)) was made. The area of each hemisphere to be sampled was delineated separately using an irregular region of interest; a cursor was used to draw the boundary of the area to be measured directly onto the image of the section as it was displayed on the monitor. The mean T_1 within the region of interest was calculated and displayed. CSF has a high T_1, and is white on the coloured display. It is therefore possible to exclude sulcal CSF by ensuring that it is not included within the boundary of the area to be sampled. In addition, the computer was programmed to present the mean T_1 of the tissues in this area that were within the range 60–600 ms. This range includes grey and white matter, but not CSF, which has a much higher value. This latter method also ensures that in the small regions of interest sulcal CSF is not included in the samples of grey matter that were analysed. Individual small areas of T_1 in the pons, mid-brain (at the level of the

optic chiasma) and posterior corpus callosum (sagittal section); frontal and occipital lobes (transverse section) and parietal and temporal lobes (coronal section) were also measured. T_1 was measured at the mid-point of each area. In each case the sample measured had a volume of 1.41 cm^3, except the mid-brain and posterior corpus callosum (0.42 cm^3).

To control for the effects of the general anaesthetic, five volunteers (three male, two female, mean age 32.6 years) had a transverse section scan before and 30 minutes after an identical anaesthetic procedure.

Results

Patients had a mean of 5.4 treatments given at a mean frequency of 2.4 per week prior to scan 3. As those having unilateral ECT did not show any lateralisation of change in T_1, unilateral and bilateral treatments have been analysed together. There was no significant change in T_1 in any of the areas examined between the beginning and the end of the course of ECT, i.e. when scan 1 was compared with scan 3 and scan 2 with scan 4.

In the transverse section there were significant differences in the mean T_1 of the whole section before and after the individual treatments, i.e. between scans 1 and 2 and between scans 3 and 4 (Table I). The mean change between scans 1 and 2 was 6 ms ($P<0.01$). The rise after bilateral ECT was larger (7.3 ms) than after unilateral ECT (4.0 ms), although this was not significant, probably because of the small numbers in the study. There was a smaller mean increase in T_1 of 4 ms between scans 3 and 4 ($P<0.05$); bilateral ECT produced a larger increase (6.7 ms) than unilateral ECT (1.3 ms), although again this difference was not significant. Patients were scanned sooner after the last ECT (15.8 ± 4 min, range 13–28 mins) than after the first (30.9 ± 16 min, range 15–62 mins), probably because by then they were less depressed and also familiar with the technique ($t=2.69$, d.f. ≐ 19, $P<0.02$); this suggested that the maximum rise in T_1 may not have occurred within 15 min of treatment. This was shown to be so in the three patients scanned six times during the six hours following ECT (Fig. 1). In the patient scanned after 25 h the T_1 time had returned to below its starting value.

The same anaesthetic sequence in the five controls was associated with a non-significant decrease in mean T_1 from 340 ms (s.d. 9 ms) to 336 ms (s.d. 8 ms).

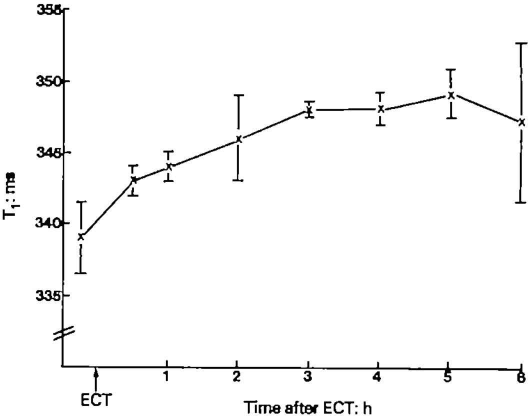

FIG. 1 Change in mean T_1 for the three patients scanned over the six hours following ECT.

Of the nineteen individual small regions in the grey and white matter, T_1 was found to increase in ten between scans 1 and 2; there was a decrease in seven, and no change in the other two. This increase was statistically significant in the frontal and occipital white matter ($P<0.05$) and in the left temporal grey matter ($P<0.01$). For the 8 patients having bilateral ECT only, there was a significantly decreased T_1 in the right occipital grey matter ($P<0.01$). Between scans 3 and 4 the T_1 in eleven regions increased; there was a decrease in six and no change in the other two.

Discussion

The mean T_1 of the transverse section showed a significant increase after treatment, both at the start and end of a course of ECT, reaching a maximum 4–6 h after the fit. This was shortlived, and no cumulative effects of ECT were noted. The increases reported in this study are likely to be underestimates of the changes produced by ECT itself, since anaesthesia alone was associated with a fall in T_1.

Measurement of the 19 small regions described above added little further information. Most of the T_1 values in the transverse and coronal sections (20 of 32) increased following treatment. Because there were 64 comparisons involved, it is likely that some of the significant differences arose by chance.

The brain stem showed a non-significant fall in T_1 in five of the six measurements. This may be due to the anaesthetic having a greater effect in this area, and is especially interesting since the brain stem reticular formation is involved in arousal.

Interpretation of changes in T_1 is difficult. There is no good evidence that ECT causes brain damage (Meldrum *et al*, 1974; Galloway *et al*, 1981), and recently necroscopy could reveal no pathology attributable to ECT in a patient who had received over 1250 treatments (Lippmann *et al*, 1985). Similarly, it is unlikely that these T_1 changes represent inflammation or brain damage, since they are reversed so quickly. It is more likely that they are the result of an increase in the total water content of the brain. It is known that ECT produces a temporary breakdown of the blood-brain barrier (BBB) and that this is probably due to the concomitant increase in blood pressure (Bolwig *et al*, 1977*a*) and cerebral blood flow (Bolwig *et al*, 1977*b*). It is also known that repeated convulsions at short intervals produce cerebral oedema (Laursen *et al*, 1985). It has been shown that macromolecules leak into cerebral tissue during the temporary breakdown of the BBB induced by ECT (Bolwig *et al*, 1977*a*). This would cause an increase in the relative osmotic pressure of the brain. After restoration of the BBB, movement of water from blood vessels into the tissues would therefore occur, and this would provide an explanation for the rise in T_1 over time. It is likely that similar changes occur after spontaneous epileptic fits, although the possibility that the observed changes in T_1 are induced by the electrical stimulus rather then by the subsequent convulsive activity in the brain cannot be excluded.

More work is needed to determine the duration and magnitude of the change in T_1 and to find out if it is related to clinical improvement or the side-effects of treatment.

In-Patient Treatment for Drug Abuse

A. H. GHODSE, M. LONDON, T. H. BEWLEY and A. V. BHAT

During 1984 there were 253 admissions to the in-patient drug dependence treatment unit at Tooting Bec Hospital. Of the 198 patients responsible for these admissions, 60% were male and 43% were over the age of 30 years. There were 151 patients admitted for opiate detoxification, and 75% completed the withdrawal schedule. However, only 15 out of 25 patients admitted for benzodiazepine withdrawals were found to be physically dependent. Other reasons for admission included stabilisation of the dose of opiate (24%) and the treatment of physical complications of addiction.

In 1965 the report of the second Brain committee recommended, among other measures, that drug dependence clinics should be set up to deal with the rising incidence of opiate dependence in the United Kingdom (Interdepartmental Committee, 1965). It was initially envisaged that in-patient units would form an integral part of treatment, offering detoxification and long term rehabilitation. Only four such in-patient units have so far been established in London and have provided a service for both voluntary agencies and out-patient clinics. The overall emphasis, however, has largely been on out-patient treatment (Ghodse, 1983). It is not clear whether this has been due to a reluctance on the part of addicts, the availability and quality of facilities, or a belief among doctors that out-patient withdrawal is preferable. In recent years there has been an upsurge in admissions to psychiatric hospitals of patients suffering from drug-related disorders. Between 1979 and 1983 the admission rate rose by 76% (DHSS, 1985).

Very little information is available on how the specialist in-patient units function. Most studies have incorporated data from these units with that from out-patient clinics (Love & Gossop, 1985). Studies that have dealt with hospital in-patients alone have been primarily concerned with the natural history of drug dependence.

The overall impression has been that these patients are highly disturbed individuals with a poor prognosis (Willis, 1969; Wiepert *et al*, 1978). Edwards (1979) has noted that the lack of current information on what actually happens to an addict once admitted for treatment has handicapped the discussion of future policies on the treatment of drug dependence in the UK. This study attempts to fill that gap by describing the experience of a major in-patient unit in London.

Method

Data was collected on all patients admitted to the Drug Dependence In-Patient Unit at Tooting Bec Hospital during 1984. This is a 26-bed in-patient unit shared between the Drug Dependence Treatment Clinics of St Thomas' and St George's Hospitals to which patients are admitted for a variety of reasons: some seek detoxification with the aim of leaving the unit drug-free, while others are admitted because of a crisis or a chaotic situation and require stabilisation of their drug usage. The medical staff of both units use a common format when recording the assessment of patients on first contact, which is usually in the out-patient clinic. This information, together with the in-patient records and relevant correspondence from clinicians, social workers and probation officers was analysed.

Results

Age and sex of patients

During 1984 there were 253 admissions to the in-patient unit, representing 198 patients of whom 37 were admitted more than once during the year.

Males constituted 60% (119) of patients. Forty-three per cent of the patients were aged 30 or over and only 8% were younger than 20.

Past history

In 38% of patients there was a history of major disruption in early life, involving death or separation of parents. Delinquency before the age of 15 was present in 51%, and 56% had left school without sitting any exams. For 56% of patients, the last partner with whom they cohabited was also dependent on drugs. For 89% there had been at least one previous criminal conviction, while 28% had six or more convictions. During the six months prior to their first or only admission, 73% of patients were unemployed.

Source of referral

Nearly two-thirds of the admissions (156; 62%) were referred from drug dependence out-patient treatment clinics, just over half of these (84; 33% of admission) from the 'home' clinics of St George's and St Thomas' and the rest (72; 28%) from other clinics that lack an in-patient facility of their own. Other sources of referral were general practitioners (37; 15%), other hospital departments and agencies (24; 9%), and self-referral (27; 11%). The source of referral was not known in 9 cases (4%).

Motivation for admission

Only 114 patients were able to give clear reasons for seeking admission. Of these, interpersonal relationships (parents, spouse, girlfriend or children) accounted for 54% (62 admissions). Physical complications of addiction accounted for 23 admissions (20%), retaining a pregnancy for 9 admissions (8%) and an attempt to obtain or retain employment for 12 admissions (11%). Although legal proceedings were said to be a motivational factor in only 8 cases (7%), 63 patients were in fact facing an impending court-case and the desire for a favourable psychiatric report for the court may have contributed to their decision to enter hospital.

Drugs of abuse and dependence

Table I shows the drugs used regularly in the month prior to admission, and it is evident that use of more than one drug is common. Drugs were obtained from a variety of sources, with 83 admissions (33%) receiving drugs from a drug dependence unit and 27 (11%) from NHS general practitioner and/or a private doctor. Only 35 admissions (14%) denied obtaining drugs illegally on the black market. It was found that 157 (62%) admissions had injected drugs intravenously.

TABLE I

Drugs used regularly in the month prior to admission

Drugs	*Admissions*	
	Number	*Percentage*[1]
Heroin	153	61
Methadone	118	47
Diconal	6	2
Other opiates	24	10
Barbiturates	23	9
Benzodiazepines	59	23
Cocaine	19	8
Amphetamines	26	10
Cannabis	59	23
Hallucinogenes	1	0
Alcohol	62	25

[1] Percentages do not add up to 100% since some individuals used more than one drug

Purpose of admission

Although the majority of patients were admitted for detoxification, 61 admissions (24%) were for the stabilisation of opiate-dependent individuals on a regular dose of methadone. Four drug dependent patients who were also epileptic were admitted for stabilisation on phenobarbitone. Occasionally, other reasons may have prompted or contributed to the admission: 24 admissions (10%) followed an overdose or a self-inflicted wound, while in 11 (4%) there had been a social crisis. In addition, 59 admissions (23%) were found to have infections which required antibiotic treatment. These were mostly skin sepsis arising from non-sterile injection techniques; 31 (12%) were found to have abnormal liver function tests.

In-patient management

On admission, a history was taken of all drugs of abuse and dependence, and a physical examination was carried out. No drugs were administered at first, but the patients were carefully observed and examined at frequent intervals. Only if there was clear, objective evidence of the abstinence syndrome was the appropriate drug administered in moderate dosage, to be repeated when withdrawal signs recurred. Signs of opiate abstinence include dilated pupils, gooseflesh, lacrimation, rhinorrhoea, restlessness and drug-seeking. Signs of barbiturate abstinence include tremor, tachycardia with increased heart-rate on standing, orthostatic hypotension, nausea and vomiting, sweating, irritability and agitation. Over a 24–48 hour period of observation it was thus possible to establish the required daily dose of the drug, which could then be administered regularly in divided doses. Once the patient was stabilised in this way, the dose of drug was gradually reduced according to a standardised regime. If a patient was physically dependent on two substances (usually opiate and sedative), stabilisation on methadone and sedative was followed by sedative withdrawal and then opiate withdrawal; alternatively, the dose of both substances was reduced, stepwise, simultaneously.

All patients admitted for opiate detoxification (151) were found to be physically dependent on opiates, and 112 (74%) successfully completed the detoxification course; of the 39 who failed to do so, 29 left prematurely of their own accord, while the rest were discharged for reasons such as violent behaviour or illicit drug use on the ward. There were 18 patients admitted for barbiturate detoxification and again all were found to be physically dependent; 17 completed detoxification. However, out of the 25 admissions for benzodiazepine withdrawal, only 15 actually required diazepam; 14 of them completed detoxification. Moreover, out of 32 patients admitted for alcoholism, only 19 required treatment; all of these completed the withdrawal schedule. Epileptic seizures were experienced by 4% of admissions prior to stabilisation on sedatives, and by 1.6% during sedative detoxification. None of the patients had fits after completion of their withdrawal schedules.

In addition to the drug regimes, patients were offered a variety of other treatments on the ward. They took part in therapeutic groups or in community meetings designed to deal with day-to-day problems on the ward. Art therapy, relaxation classes and individual counselling were also provided.

Outcome

Once patients had successfully completed their withdrawal schedules, they were encouraged to give careful consideration to their immediate future. Those who were especially vulnerable to relapse were asked to consider entering a residential rehabilitation programme, and social workers helped them to choose an appropriate plan for their future. The choice of entering a therapeutic community was made by 5% of all admissions, and 38% decided to opt for out-patient follow-up in the drug dependence clinic. The decision to discharge themselves against medical advice was made by 46% of admissions, although two-thirds of these had successfully completed their withdrawal schedules. Patients were advised to remain for a minimum of two weeks following detoxification, because it was felt that immediate return to the community held a high risk of relapse, but many were impatient after the weeks spent on a closed ward, and left against medical advice. The disposal of the remaining 12% of admissions varied. Many returned to the care of their general practitioners, while some moved to a different geographical locality.

The duration of the admissions varied widely: 6% of admissions ended within the first 24 hours while 7% lasted longer than three months. A third of all admissions remained in hospital for more than four weeks.

Discussion

Patients admitted to hospital for the treatment of drug dependence are generally those who are too severely dependent for out-patient management. Although estimation of the severity of dependence is a complex issue, one indication of the severity of dependence of these patients was that more than a third of all admissions in 1984 were re-admissions within that 12-month period.

Although 43% of the admissions were aged 30 years or more, a contemporary study of referrals to a London out-patient drug dependence clinic showed that only 35% of patients were in this age group (Love & Gossop, 1985). In the UK as a whole, only 22% of addicts notified to the Home Office in 1984 (and whose age was known) were aged 30 years or more, and 15% were under the age of 20 years. These differences may arise because London, with a longer history of drug abuse, has an older population of addicts than occurs in other parts of the country. Alternatively, or in addition, a possible explanation for the difference may be that clinicians were reluctant to admit younger patients to an environment where they would be in prolonged and close contact with seasoned addicts, or again, younger patients may not perceive in-patient treatment as relevant to themselves.

The purpose that lay behind the majority of admissions was the treatment of opiate dependence. All these patients were found to be physically dependent on opiates, and 74% of those admitted for opiate detoxification completed their withdrawal schedule. For such a disturbed group of patients this is a high success rate and similar to that reported by Gossop *et al* (1986).

The pattern of addiction to sedatives has altered over the years, with the decline in barbiturates being replaced by a rise in benzodiazepine abuse. Indeed, benzodiazepines were identified in the urine of 60% of patients attending a drug dependence out-patient clinic, and 76% of these had obtained their drug illegally (Beary *et al.,* 1987). Altogether, out of 37 patients admitted for sedative (benzodiazepine and/or barbiturate) detoxification, 28 were dependent on opiates. The proportion of patients who gave a history of barbiturate usage and the proportion who were subsequently found to be addicted were roughly the same, whereas only 15 patients (25%) of the 59 who gave a history of regular benzodiazepine use showed signs of physical dependence. Most of those who proceeded on to sedative detoxification completed their schedules, probably because it was unit policy not to allow patients to leave in the middle of a withdrawal schedule because of the risk of fits.

Most drug addicts are users of more than one drug, and alcohol is one of the substances frequently abused; it may then become one of their drugs of dependence. Stimulants are also commonly abused, and it is noteworthy that cocaine was used almost as frequently as amphetamines, probably reflecting the recent rise in its use.

In-patient treatment tended to fall into two stages; the initial period of drug withdrawal, when the patient was mainly preoccupied with his or her symptoms, and the subsequent period of recovery and planning for the future. Owing to the lack of facilities, patients entering the second stage were forced to remain on the same locked ward. Many resented this continued restriction and many of the self-discharges occurred during this phase.

The in-patient unit of the drug dependence clinic provides a valuable service, particularly for those addicts who are the most seriously ill. Of those who entered hospital, a high proportion were successfully stabilised or withdrawn from drugs. However, this should be regarded as only the first step in the rehabilitation of the patient, and this study does not provide information about the long term outcome for the patients concerned. Nevertheless, a re-structuring of the in-patient facilities to mirror more accurately the two-stage nature of the treatment offered may improve the outcome as far as long term rehabilitation is concerned. The recent rise in drug addiction has resulted in more resources becoming available to treatment agencies, but the bulk of these have been allocated to community projects. Equal importance should be attached to improving in-patient facilities, so that a better standard of care can also be offered to the more severely ill and disturbed patients that these units serve.

The Munchausen Syndrome and its Symbolic Significance:
An In-depth Case Analysis

A. CREMONA-BARBARO

The 'gains' of Munchausen syndrome cannot readily be understood on a rational level, and are presumed to be intra-psychic. The presenting fabrications often follow a remarkably similar pattern, and some psychodynamic insight might be gained by analysis of the general themes and contents. The case of one typical patient is reported here, and the aetiology and symbolic significance discussed.

Munchausen's syndrome was first described by Richard Asher in 1951. It is a condition in which patients repeatedly present themselves at different hospitals, often far apart, often using different names, making up colourful histories, and describing various fictitious signs and symptoms in order to gain admission to hospital. Once admitted, they submit themselves to painful and dangerous investigations, operations, and treatment, disappearing only when they are found out. Asher wrote that "The most remarkable feature of the syndrome is the apparent senselessness of it all. Unlike the malingerer who may gain a definite end, these patients often seem to gain nothing except the discomfort of unnecessary investigations and operations". Furthermore, these patients sometimes die as a result of their 'dicing with death' (Enoch & Trethowan, 1967).

Much has been written about these patients' self-destructiveness, and various interpretations have been attempted. Although their manipulation appear to be conscious, the underlying motivations must be unconscious; the gains cannot be understood on a rational level and must be presumed to be intra-psychic. Various interpretations of this behaviour have been made, including a need to suffer and perhaps to die, a desire to be the centre of attention, the adoption of a passive controlling role, the cheating of an authority or parent figure, dependency needs, erotic desires, symbolic castration, hatred of doctors, maternal mishandling of early childhood illness, abnormal care-eliciting behaviour, a desire to obtain shelter, money, or drugs, psychopathy, depression, and a desire for a new life with a new name (Berney 1973, Blackwell 1968; Cramer *et al*, 1971; Enoch & Trethowan, 1979; Henderson 1974; Ireland *et al*, 1967; Menninger 1934; O'Shea *et al*, 1984; Reed 1978; Spiro 1968). Certainly it would appear unlikely that the syndrome is a simple case of hospital addiction, need for board and lodging, attention-seeking behaviour, dependency needs, or abnormal care-eliciting behaviour, as these patients inevitably discharge themselves following discovery, even if offered an alternative. In-depth analysis of cases has therefore proved difficult.

However, these patients' fabrications often follow a curiously similar pattern, and some psychodynamic insight might be obtained by closer examination of their general theme and content. The most common story, usually accompanying an overdose or some other variant of self-destructive behaviour, is of a feigned and dramatic bereavement. These stories often bear a striking resemblance to tragic opera, and indeed, these patients frequently exhibit a preoccupation with the operatic world, e.g. giving their occupation or that of the deceased relative as 'opera-singer', or claiming some other connection with the opera or the ballet. We have recently seen a Munchausen patient who gave this typical story and who, following discharge, corresponded briefly with the hospital chaplain. The theme of these communications was primarily the opera and the ballet. It seemed interesting to examine these leads more closely, in an attempt to shed light on this fascinating condition.

Case Report

Paul K, a male aged 46, was admitted following a paracetamol overdose, which he claimed had been precipitated by the death of his wife and only daughter in a road traffic accident in Tunisia, three weeks earlier. He described his shock when the news of the death was broken to him, and also told of the horror of having to examine the bodies in the mortuary. He expressed gratitude at being able to tell the story to the doctors and nurses, and said that he recognised his need to speak to people in this way. His past history included a story of a massacre on his father's plantation in Kenya, in which two servants were decapitated.

On examination, he was anxious and shaky, but was described by the nursing staff as being very pleasant. However, when attempts were made to contact the patient's reported general practitioner and place of work, it was discovered that neither of these had ever heard of him. He discharged himself before this could be discussed with him, but left a letter with the hospital chaplain, together with a list of what he felt were the significant events in his presumably real life; he thanked the chaplain for his care, and apologised for any trouble that he had given. In his view, the answer to his conundrum is not known by any medical or psychiatric mind, but that one person who has the answer is a 19th century Italian composer, Gaetano Donizetti in *L'Elisir d'Amour* (*Elixir Of Love*).

The list of attitudes and events suggested that he had never received or given love, but that ambition drove him to conform to social norms and to marry and have children until, at the age of 42, a life crisis involving guilt caused him to sacrifice his ambition. Three years later, he described his own 'death', by which he presumably meant a symbolic and emotional death resulting from, or possibly causing, the losses of his wife's companionship, his own drive, and his ambitions for his children. He concluded that love and grief were absent, and that this resulted in guilt.

A few days later, the chaplain received another letter from the patient, from Manchester, stating that he had not found any answer in *L'Elisir d'Amour* after all, but that he was going to try the ballet *Romeo and Juliet* instead. Two days later, another letter arrived, saying that *Romeo and Juliet* had also proved negative, but that he was going to Paris to try *Tristan and Isolde*; this story, like *Der Fliegender Holländer* (The Flying Dutchman) and *Götterdämmerung* (Twilight of the Gods), was based on Wagner's Theory of *Liebestod* or 'love though death'. The last card arrived three days later, and stated that Paris had also been negative, but that he was moving on to Munich to try Richard Strauss's opera *Tod und Verklärung* (*Death and Transfiguration*).

The operatic themes

To understand the patient's meaning and solve the riddle, it is necessary to know something about the operas and ballet mentioned by him, though the story of *Romeo and Juliet* requires no explanation.

L'Elisir d'Amour is a comic opera written by Donizetti in 1832. Nemorino drinks a love-potion in order to win Adina, but in the meantime, accepts the hand of another. The news then spreads that Nemorino's uncle has died and left him a legacy, and in consequence, he is besieged by the attentions of all the girls in the village. Adina also becomes conscious of her love for him, and after some misunderstanding, the lovers are united.

The next group of operas are all by Wagner: *Tristan and Isolde, The Flying Dutchman*, and *Götterdämmerung*. The story of *Tristan and Isolde* opens on board a ship, where Isolde, who is being taken to Cornwall against her will to marry King Mark, resolves that she and her military escort, Tristan should die. She tricks him into drinking a death-potion, which she shares with him, but unknown to them both, a love-potion has been substituted instead. In the face of certain death, they become conscious of their mutual love, and are able to confess it. However, due to the substition of the potion, they do not die, and arrive safely in Cornwall, where the frustrated lovers long for death, since only through that can they be united and their love realised. When discovered in an embrace with Isolde, Tristan fails to defend himself, and is badly wounded, dying in Isolde's arms, and Isolde's *Liebestod* starts. This is the longing and readiness for death, combined with love-ecstacy, which results in Isolde's transfiguration and death, as she sinks to the ground over Tristan's body.

The Flying Dutchman contains the same theme of redemption through love and death. The Dutch captain was condemned to sail the seas forever, unless redeemed by the love of a woman who will be faithful to him unto death. He meets Senta and becomes betrothed, but due to a misunderstanding, believes that she has been unfaithful to him, and orders his ship to set sail. Senta, determined to save him, throws herself into the sea, crying "See, I am faithful to you unto death", and at the same moment, the ship sinks, and he and Senta are seen rising into the heavens, clasped in an embrace.

The third opera is *Götterdämmerung*, the tragedy which culminates the *Ring Cycle*. The Gods and the World are doomed through greed and corruption, and can only be saved by the return of the Rhinegold, now made into a ring, to the Rhine-maidens. Siegfried who possesses the ring, is betrothed to Brünnhilde, a Valkyrie.

However, he is given a magic potion, which causes him to forget Brünnhilde, and ask for the hand of Gutrune; Brünhilde therefore conspires to kill Siegfried, and reveals that he is only vulnerable to attack in the back. He is consequently murdered while two ravens, the symbols of transformation, circle above his head. His dying words are of Brünnhilde's awakening, and he calls out that he is wakening her again and that this time her eyes are open forever, implying an eventual rebirth following her impending death. The implication of life after death is continued when an attempt is made to tear the ring from Siegfried's finger, and the dead man raises his hand threateningly.

This leads to the theme of redemption. Brünnhilde knows that redemption can only be achieved by the return of the ring to the Rhine-maidens, and resolves to do this. She commands that she and Siegfried should be burnt on a pyre, and takes the ring. The flames engulf them, and at the same time, the Rhine overflows its banks and surges forward with the Rhine-maidens on its waves, so that the ring is returned to them. The fires are seen to devour Valhalla, thus allowing the rebirth of a more hopeful phase.

The last work has the telling name *Death And Transfiguration*. This tone poem depicts the bodily dissolution of a hero who in his last moments sees the happiest events of his life pass before his mind's eye. A poem by Alexander Ritter was later published with the score, describing the *'lamento e trionfo'* of the hero's death. The main theme has been described as "not resignation but contented leave taking".

Discussion

The basic theme underlying all these stories, most of which are derived from ancient mythology, seems to be that of transformation, redemption, and the triumph of love, achieved either through the voluntary embracing of death or imbibing magical potions. This theme is one that recurs time and again in the traditions, religions, myths, and legends of many different cultures, from the primitive sacrifices of Stone-Age man, to Phoenix arising from the ashes, through to Christ redeeming us by his death and subsequent reincarnation.

Robert Donnington, in his book *Wagner's Ring And Its Symbols,* writes: "These outward deaths are often depicted literally in dreams, fantasies, myths and legends, but their true meaning is almost certainly inward pain and death". Wagner himself wrote: "The period in which I have worked in response to my intuition starts with *The Flying Dutchman* and if in these works there is any underlying poetic theme, it must be looked for in the supreme tragedy of renunciation, the abnegation of the will, which is shown there as necessary and unavoidable, and alone capable of achieving redemption". Donnington understands redemption to be a synonym for transformation—"None of Wagner's images in *The Ring* actually point to annihilation as our own Western thoughts conceive it. One after another of them points to rebirth in the sense of transformation"; this would appear to be true in the suicide or voluntary sacrifice of life of Tristan and Isolde, Senta and the Dutchman, and Siegfried and Brünnhilde, in each of the three Wagnerian operas referred to, as well as that of Romeo and Juliet in the ballet mentioned by the patient.

It is interesting to attempt to relate some of this to what we know of Munchausen patients. Enoch & Trethowan (1979) said of Munchausen syndrome that "the disorder is characterised by a relentless tendency towards self-destruction", and it would seem to be this which chiefly distinguishes the syndrome from malingering and hysteria. Time and again, these patients put themselves into situations in which they suffer. One can only speculate about the psychodynamic mechanisms, but it is tempting to attempt to explain the relentless masochistic self-punitiveness and 'dicing with death' as an unconscious attempt to appease the gods, prove overwhelming remorse, and obtain absolution and redemption by killing the old self or a part of it, to allow transformation from despised self to ego-ideal, and hence the attainment and inspiration of elusive love and perfect happiness. Menninger (1934) described certain patients in whom "the capacity for dealing with reality is so poorly developed, that they proceed as if they could actually kill themselves and not die". Pseudologia phantastica may be yet another form of this calculated risk-taking, and in addition the difference between reality and the rather grand abilities, qualities, and qualifications which these patients claim for themselves probably also reflects the discrepancy between self-image and ego-ideal and the need to inspire admiration. It may also satisfy the need, arising from this poor self-image, to deceive 'intelligent' professionals.

Snowden *et al* (1978) said of their Munchausen patients: "In some cases it seemed as though the patients were seeking a new life with a new name to get away from themselves and their problems", and Deutsch (1955) that "In one act he searches for a new identity and denies his own real identity". Such an instinctive and powerful belief in atonement and salvation may well spring from the forces of an ancient and deeply-rooted collective unconscious which, over the ages, has given rise to a variety of myths and is now surfacing again and being acted out in a primitive and concrete way. Indeed, there would seem to be too many similarities in the content of the Munchausen stories for this to be purely coincidental. The feigned death of spouse or family may also have as its source, as in so many of these operas, the need for the symbolic sacrifice and death of both partners before unity and love can be achieved.

Cramer *et al* (1971) wrote of Munchausen patients: "Their pathomimicry may be a last ditch attempt at warding off further disintegration". Ireland *et al* (1967) noted that the self-destructive behaviour may "serve to allay intolerable anxiety", and "focal self-destruction may represent atonement for an overwhelming sense of guilt." Menninger (1934) speculated that "Guilt prevents them from accepting love", and also suggested that the behaviour may be "an anti-suicide, a last-minute attempt at saving the whole by sacrificing a part". There is also an element of passive suicide, in that the actual responsibility for the destructiveness is relinquished to the surgeon; it may be this which make it necessary to use the hospital as a stage. Menninger compares this to an animal with its foot caught in a trap, who gnaws off his own leg to get away. Sometimes a more direct attempt of annihilation is made: "The Munchausen patient, at a time of unusual stress, resorts to surrender of the whole in the form of attempted suicide" (Ireland *et al*, 1967). Justus *et al* (1980) carried out an MMPI on a Munchausen patient which concluded: "There are also indications that he is harbouring a great deal of angry affect over which he may be experiencing considerable guilt. As such it may be turned inwards in the form of depressed affect and/or self punitiveness". Guilt would certainly seem to be prominent in our patient, who himself concluded "Guilt positive" at the end of his list of life-events.

When a diagnosis of Munchausen syndrome is made, there is almost always some implication or allegation of anti-social behaviour, but when viewed from this wider perspective, ego-weakness turns to ego-strength in a transformation every bit as dramatic and magical as the ones already described. The accompanying deceit, which stimulates so much contempt and anger, then appears not as a primary goal, but as an incidental by-product of a powerful instinctive drive towards intra-psychic gains.

It is difficult to assess how much of the Munchausen behaviour is conscious or unconscious, since much depends on the observer's point of view, and the syndrome probably lies on the borderline between the two. However, the importance of making this distinction is uncertain. In general, we tend to equate 'voluntary' with 'conscious', but in our everyday life, all of our 'voluntary' actions are to some extent influenced by unconscious factors. We are also accustomed to assume that unconscious falsifications of illness indicates psychopathology, while the possession of insight into that falsification indicates a voluntary element, and therefore psychopathy. It is possible that this falsification may be partly conscious but not wholly under the 'patient's' control, and that it indicates neither psychopathy nor necessarily psychopathology. Spiro (1968) has suggested of the Munchausen patient that "he knows when he is acting, but even with this knowledge he can not stop acting". He likens these patients to alcoholics and drug addicts: "Seemingly wilful acts are determined by unconscious factors and environmental ones to produce a psychiatric illness of profound dimensions". On the other hand, Szasz (1961) refers to "the logical dilemma of the existence of an alleged entity called mental illness which even when deliberately counterfeited is still mental illness". The problem lies largely in the fact that what we call illness is to a great extent selected by society and doctors.

The role of a sick person in society is also relevant. It has been said that everyone exaggerates or feigns ill-health at times, for a variety of reasons, including the avoidance of minor responsibility, denial of failure, and to evoke caring within our family and social network. Parsons (1951) has pointed out that once a person's illness has been medically sanctioned, that person occupies a special role, and is relieved of the usual demands and obligations made on him, while Mechanic (1962) has shown that medical facilities are more likely to be used by persons highly stressed in terms of loneliness and nervousness. The doctor's role complements this, in that he assumes responsibility for the patient's illness and cure (which may include responsibility for the intra-psychic cure, in the form of surgery), and provides a relatively easy way for the patient to communicate and temporarily relieve his sense of isolation. Traditionally in a doctor-patient relationship, the patient has needs and the doctor offers services which go beyond technical medicine.

It is also likely that the aetiology of Munchausen syndrome is multi-factorial, and that no single psychopathological factor accounts for all cases. However, it may be appropriate to view the behaviour in some cases as adaptive, rather than maladaptive in a psychodynamic sense, and it would be interesting then to interpret the patient's behaviour to them in these terms.

Anorexia Nervosa in Males
A Comparison with Female Patients

J. L. MARGO

The demographic features, clinical picture, antecedent events and family background in 13 male patients with anorexia nervosa are compared with those in a control group of 39 adolescent female anorectics; the general picture of the illness in males is similar to that in females. Focusing on a group of males, usually less vulnerable to anorexia nervosa, can highlight possible predisposing factors.

Anorexia nervosa (AN) is predominantly an illness of girls and young women, but it is estimated that 5–10% of all cases occur in males (Hay & Leonard, 1979; Andersen & Mickalide, 1983; Crisp & Burns, 1983). It is of value to present a series of male cases for two reasons. Firstly, males presenting with AN are still relatively rare, and most published accounts consist either of individual case reports or of small series of patients. Further investigation of their features is necessary, particularly in comparison with typical female patients. A more important reason, though, concerns aetiological factors: the rarity of the illness in males may indicate that they have a degree of protection from the condition, and it could be argued that predisposing or precipitating factors will therefore be more prominent in those males who do actually develop it. While the possibility of there being qualitative sex-determined differences in aetiology between males and females with AN cannot be ruled out, from the clinical and diagnostic point of view the illness in the male is generally seen to resemble that in the female (Beumont *et al*, 1972; Vandereycken & Van den Broucke, 1984). If this can be confirmed, it seems reasonable to assume that the same major aetiological factors also operate in both sexes.

The investigation of a series of male patients provides an opportunity to identify such factors. This paper presents the features of 13 male patients with AN, and compares them with a series of 39 typical adolescent female anorectics, studied in a similar way.

Method

By a manual search and with the help of the Oxford Record Linkage Study, an attempt was made to identify all male patients seen since 1967 in the Oxford psychiatric hospitals who had received a diagnosis of AN. Their case-notes were then scrutinised, and if the criteria for a diagnosis of AN were met, relevant details were recorded. The diagnostic criteria were modified from those of Feighner *et al* (1972) and were

(a) a distorted implacable attitude to food, eating or weight
(b) weight loss of at least 25% of original weight, or the attainment of a weight 25% or more below that expected. Expected weight was calculated from standard actuarial tables (Geigy, 1962) for patients aged 15 and over, and from height and weight standard charts (Tanner & Whitehouse, 1975) for younger patients
(c) the absence of any medical or other primary psychiatric disorder which might account for the anorexia or weight loss
(d) the presence of at least one of the following: loss of sexual interest, lanugo, bradycardia (sustained at ⩽60/min), overactivity, bulimia, vomiting.

Findings for these patients are compared, where relevant, with those for 39 females in a series of adolescent patients presented in more detail elsewhere (Margo, 1985, 1987).

Results

Demographic features

Between 1967 and 1983, 13 male patients fulfilled the diagnostic criteria. All were Causasians. Because they came from a number of settings, it was difficult to ascertain what proportion of the total number of AN cases they represented. However, the three adolescent patients seen up to 1979 represented 7% of all adolescent anorectic patients seen at the Warneford Hospital and Highfield Adolescent Unit in this period and diagnosed according to the same criteria.

Twelve of the 13 patients were referred in the second half of the period studied (1976–83). Age of onset of illness ranged from 13.8 to 35.1 years, with a mean of 20.0 years. Seven patients were aged under 18 at onset; three were 18–25, and three were over 25 years. Eleven patients had never married; two were married, one with no children and the other with three.

Five patients came from social classes I and II (Registrar-General's classification; Office of Population Censuses and Surveys (1985)) and eight from social classes III, IV and V; this was not significantly different from the expected distribution for Oxfordshire. Not only did this group of patients fail to manifest the usual upper social class predominance of AN, but the males showed a statistically significant relative preponderance of lower social class patients compared with the female group ($\chi^2 = 2.71$, d.f. = 1, one tailed $P = 0.05$).

Clinical features

Weight losses of up to 50.4% of original weight were recorded (mean 33.7%) and weights were up to 47.5% less than expected (mean 35.4%). In 3 patients lanugo was recorded as a clinical feature; loss of sexual interest was noted in 6, bradycardia in 7, overactivity in 8, bulimia in 3, and vomiting in 4.

The only statistically significant difference in the occurrence of clinical features in males and females was the notably more common presence of overactivity in males (62% against 26%; $\chi^2 = 4.08$, d.f. = 1, two tailed, $P < 0.05$).

Of the nine patients whose heights were recorded, six were under the 50th percentile (Tanner & Whitehouse, 1975). Four of these were under the tenth percentile (binomial test, $P = 0.008$), including two whose heights were less than the third percentile. This is in contrast to the female group, in which there was a significant excess of tall girls (over the 90th percentile).

The time from onset of illness to referral to a specialist agency was variable – from 1 to 57 months. Although the proportion of cases referred to a specialist agency within six months of onset was similar to that for girls (50% and 57% respectively), the average delay before referral was far longer for males – 12.5 months, compared with 7.4 months. This was because when males did have a delay of over six months before referral, it tended to be a long one – over a year in two-thirds of these cases.

Antecedent events

In seven patients it was possible to identify major life events in the year preceding onset which were thought to be of relevance to the development of the illness. Examples were loss or threat of loss of friendships, illness of a parent, or disruptions in family relationships caused by events such as an unexpected pregnancy in the mother or the relationship between father and sister leading to the latter being placed in care. In addition, three patients complained of being teased because of their size (in one case this was small stature and lack of physical development rather than obesity) and two patients were reported to have suffered a 'flu-like illness shortly before the onset of AN. These findings are similar to those in the female group.

Premorbid obesity was defined as a weight at some time before the onset of the illness that was 25% or more above that expected for the patient's age and height, or (if height was not known) a weight over the 97th percentile for his age: it was a feature in four patients. This was much higher than the 10% in the female group, but the difference did not reach statistical significance.

Family background

Age of parents. Information was available for 12 sets of parents. Ages of mothers at birth of their anorectic children ranged from 20 to 39, with a mean of 28.3 years. Those of fathers varied from 25 to 40, with a mean of 31.3 years. The mean difference in parental ages was 3.1 years. Unlike the mothers of the female patients, the parents of this group were not older than expected, according to the available national statistics.

Family composition. Unlike the female group, these patients come from larger than expected families, the mean number of children being 3.25, against an estimated expected number of 2.4 (Farid, 1974). Only one was an only child, while five came from families of four or more children. The female: male ratio among the siblings of the patients was 12:17. As in the female group, anorectics did not appear to occupy a particular place in the birth order.

Family history of mental illness. A positive history of mental illness (defined as the identification of a condition for which there was evidence that some form of active management had taken place) was present in a parent or sibling of five patients (38.5%). If grandparents and parental siblings were included, a positive history was found in 14 relatives of six patients (46.2%). The corresponding percentages in the female group were 23.1% and 30.8% respectively. In all cases in which a diagnosis was available, the illness seemed affective in nature.

Abnormalities in the family setting. Such abnormalities (as defined in Margo, 1987) were noted in five patients. These included problems such as chronic parental marital difficulties, the death of a parent and problems with a stepmother and stepsiblings, and chronic mental illness or physical handicap in a parent. In addition, one patient had a mother who had become a persistent dieter before the onset of his own illness. These results are similar to those found in the female group.

Discussion

As in the female group, there was an increase in the referral rate from the mid-1970s, although whether this reflects an actual increase in the prevalence of AN remains unclear (Margo, 1985). Bruch (1974) believed that AN in males was pre-pubertal in onset, but this has been refuted by a number of studies which have shown that, as in females, the condition in males begins mainly in adolescence (Beumont *et al*, 1972; Dally & Gomez, 1979; Crisp & Burns, 1983; Vandereycken & Van den Broucke, 1984). The latter was confirmed in this study, although three patients were over 25 at onset. The male patients in this series failed to manifest the usual upper social class predominance seen in female patients; this finding does not accord with a recent comparison of male and female patients (Burns & Crisp, 1984), and its validity is uncertain.

Of the clinical features, overactivity was significantly more often recorded in the male group than in the female control group, and appears to be a common symptom in males with AN (Beumont *et al*, 1972; Taipale *et al*, 1972; Bruch, 1974; Hogan *et al*, 1974; Sheppard *et al*, 1984; Ziesat & Ferguson, 1984). This may be because physical activity and exercise are more culturally acceptable methods of losing weight for males than females. The incidence of loss of sexual interest in this series was relatively low, compared with that in other studies (Beumont *et al*, 1972; Dally & Gomez, 1979; Crisp & Burns, 1983). A major reason for this is that in five of the 13 patients, information on this point was not available in the case-notes. Clinicians ought not to be shy of pursuing questions about sexual interest, particularly as patients often welcome or are indifferent to their loss of libido while ill, and may not volunteer it as a symptom (Crisp & Burns, 1983).

It was notable that in four of the nine cases in whom heights were recorded these were under the tenth percentile; this contrasts with the excess of very tall girls in the female group. Reports of heights in other series of male anorectic patients are inconsistent: although heights were unremarkable in some series (Dally & Gomez, 1979), Bruch (1974) reported that three of her six primary cases were of very short stature. A number of case reports suggest that AN stunts growth, particularly in males (Toms & Crisp, 1972; Root & Powers, 1983) – i.e. that short stature in anorectic patients ought to be seen as secondary to the illness. Although this is sometimes true, it does not appear to be so in all cases and could not be shown to apply in any of those reported here; in three of the four short patients the stature clearly antedated the onset of the illness. One of the patients dated the beginning of his preoccupation with his size and appearance to being teased by his peers about his small stature. While females in our culture are under pressure to control their size and be slim, males prefer to be larger and heavier (Hsu, 1983). Thus the small male, like the large or very tall female, risks becoming preoccupied about his size and deviation from what he considers a desirable physique. This dissatisfaction with appearance may lead to psychological conflicts or low self-esteem being focused on the body, and may in turn be a risk factor for the development of AN, control over the body becoming confused with control over wider issues.

The long delay before referral to specialist services in those patients in whom the illness was not recognised early is a matter of some concern: long duration of illness is associated with poor prognosis, both in males specifically (Burns & Crisp, 1984) and in AN generally (Morgan *et al*, 1983). Resistance to treatment among male patients (Crisp & Toms, 1972) and the lesser degree of public and medical alertness to the condition in males are probably the major causes of this problem.

As in females, significant life events appeared to be common antecedents of the illness. Premorbid obesity was more common than in the female group; a similar high incidence was reported in a number of other studies of males, although definitions of obesity vary (Falstein *et al*, 1956; Beumont *et al*, 1972; Hogan *et al*, 1974; Anderson & Mickalide, 1983).

Unlike those of the females, the mothers of the male patients were not older than expected. However, relationship and other difficulties within the family were shown to be common here, as in the female group. Many studies of males with AN have commented on the high prevalence of such difficulties, e.g. severe parental marital disharmony (Taipale *et al*, 1972; Sreenivasan, 1978; Dally & Gomez, 1979; Hay & Leonard, 1979; Sheppard *et al*, 1984). A history of psychiatric illness in the families was frequent, affecting almost half the patients: since this is a case-notes study, the true figure may be even higher. The positive family history was on the mother's side in five cases and on the father's once; when parents were involved, four were mothers and one a father. A similar pattern has been reported elsewhere (Crisp & Toms, 1972; Dally & Gomez, 1979). Psychiatric illness in the family – particularly in a parent – has a potential pathogenic effect over and above the purely genetic, such as by disrupting family relationships or causing episodes of parental separation.

From this series, the impression that AN in males is essentially similar to the condition in females is largely confirmed. The second object of the study was to examine whether factors of aetiological significance might be more clearly highlighted in a male group of patients. Possible factors would be those prominent in the female group and occurring at least as commonly, and probably notably more commonly in the male group. According to this argument the aetiological significance of, for example, the finding that anorectic females have older mothers (Margo, 1987) is called into question by the failure to confirm this finding in the male sample. On the other hand, features such as significant life events and abnormalities in the family are found consistently in the backgrounds of many anorectic patients, and were prominent again here. However, such factors as life events may often act as precipitants, so that the underlying causes of vulnerability need to be sought elsewhere. AN is unlikely to have one single or necessary aetiological factor, but instead would seem to be predisposed to by a number of vulnerability factors, whose relative importance cannot yet be determined. This study does point to two, in addition to those already mentioned – a family history of psychiatric illness, and a deviation from the perceived 'normal' body shape.

The importance of a family history of psychiatric illness emerged strongly in the male patients: nearly half had such a history, predominantly of the affective type. This supports the view that there may be some relationship between AN and affective disorder (Cantwell *et al*, 1977; Winokur *et al*, 1980; Hudson *et al*, 1983), although the nature of the relationship is complex and needs further elucidation (Hsu, 1983). If the inherited or environmental effects of such a family history contribute to a general psychological vulnerability, the question still to be answered is why such a vulnerability should under stress manifest itself as AN. It is possible that anything preoccupying a vulnerable individual with dissatisfaction over bodily appearance will in time lead to the body becoming the focus for all his or her emotional conflicts, and predispose to the development of AN: premorbid obesity appears to be a not uncommon feature in male anorectics, and often serves as such a factor. The possible role of short stature in males (or large stature in females) in this regard has already been discussed.

Acknowledgements

I thank those consultants who allowed me to look at the case-notes of patients under their care, and I acknowledge the assistance in tracing cases received from the Oxford Record Linkage Study, particularly from Dr J. de Alarcon.

Specific Cross-Gender Behaviour in Boyhood and Later Homosexual Orientation[1]

R. GREEN, C. W. ROBERTS, K. WILLIAMS, M. GOODMAN and A. MIXON

Data from a group of males aged 13 to 23, who as children exhibited extensive cross-gender behaviour, was analysed. In boyhood they frequently played with dress-up dolls, role-played as females, dressed in girls' clothes, stated the wish to be girls, primarily had girls as friends, and avoided rough-and-tumble play. The majority of the group evolved a bisexual or homosexual orientation; two types of behaviour, boyhood doll play and female role-playing, were found to be associated with later homosexual orientation. The findings suggest developmental associations between specific types of boyhood cross-gender behaviour and the objects of later sexual arousal.

When interviewed as adults, male homosexuals recall patterns of boyhood feminine behaviour more often than do male heterosexuals. They commonly report, as children, having: role-played as females, worn girls' or women's clothes, avoided male playmates, avoided conventional rough-house boyhood games, and wanted to be girls (Harry, 1982; Bell *et al*, 1981; Whitam, 1977; Saghir & Robins, 1973). These investigators suggested that such cross-gender behaviours are likely to endure in the form of adult homosexual orientation, but their studies used retrospective data, which are likely to involve errors of selective recall or reconstruction as subjects report their pasts. By contrast, two reports have utilised follow-up data on previously 'feminine, boys. In one, interviews with 16 adult patients described in medical records made during childhood as showing 'feminine' behaviour revealed two to be homosexual, three to be transsexual, and one a transvestite (Lebovitz, 1972). However, the extent to which these adults were representative of all males previously described as 'feminine' in those records is not clear. In the other report, a group of 55 males seen earlier for 'feminine' behaviour in boyhood or early adolescence was re-evaluated; about two-thirds of the group was reported to be homosexual (Zuger, 1984), but it is not clear how many who are currently homosexual were pre-adolescent when initially evaluated, and there is no report of how many of the 'homosexuals' are exclusively homosexual, predominantly homosexual, or bisexual. Most importantly, from the standpoint of the present study, there is no report of the association between specific features of boyhood 'femininity' and later sexual orientation.

The findings presented here examine whether specific boyhood gender-typed behaviours are related to later sexual orientation. We assessed a group of adolescent and young adult males (aged 13 to 23) who had displayed cross-gender behaviour in boyhood; each boy had been previously evaluated before the age of 12.

Sample

Our data derive from a clinical group of 66 families evaluated at the UCLA Gender Identity Clinic between 1969 and 1974. Families were evaluated after parents presented with the complaint that their sons were 'feminine', and were included in the group if the boys displayed extensive cross-gender behaviour. Most of the boys, more than occasionally, stated their wish to be girls or to grow up to become women. They avoided the traditional sex-typed activities of boyhood (such as rough-and-tumble play and sports), preferentially role-played as females, and preferred the clothes, toys, companionship, and games of girls (Green, 1974, 1976). They were anatomically normal (not intersexed). A comparison group of 56 families was solicited by newspaper advertisement, and selected by demographically matching each family to a family with a 'feminine' boy. Families were matched by age of son, sex and age of siblings, and race, religion, education, and marital status of parents. Fifteen years after the collection of initial interview and questionnaire data began, follow-up data on sexual orientation have been collected on about two-thirds of the boys (previously 'feminine' boys $n=44$; comparison boys $n=35$). Contact was lost with or terminated by about one-third of the families.

Method

Following Kinsey *et al* (1948), sexual orientation was rated on a seven-point scale ranging from exclusive heterosexuality (0) to exclusive homosexuality (6). On this scale, 1 is incidental homosexuality, but nearly all heterosexuality.

---

[1] An earlier version of this paper was presented at the annual meeting of the American Sociological Association in San Antonio, Texas, August 1984.

TABLE I

Items related to boys' atypical sex-typed behaviour

Category	*Variable name*	*Wording*	*Typical scoring*	*Whether from interview (I) or questionnaire (Q)*
Doll/role play	ROLEPLAY	Does he play "house" or "mother-father" games? What role does he take?	1 = always male, never female 6 = always female, never male	I
	PLAYHS	When playing house my son usually assumes the role of . . .	1 = father, brother, himself, or other male 3 = mother, sister, or other female	Q
	DOLLPLAY	What are his favourite (next favourite) toys?	1 = no dolls, but trucks, etc. 6 = constant play dolls)	I
	DOLPLAY	My son plays or has played with dolls . . .	1 = never 4 = favourite toys	Q
Cross-dressing	XDRESS	I have observed my son or have received reports of my son wearing an article of feminine clothing (including jewellery or makeup) . . .	1 = never 3 = frequently	Q
	NOXDRS	I have observed my son or have received reports of my son dressing up in feminine clothing the following number of times:	Score = actual number	Q
	IMPROVS	My son has improvised (designed from other materials) the following feminine clothing:	0 = none 1 = one type 2 = two or more types	Q
	INTEREST	Does he seem to show any unusual interest or preoccupation with types of cloth or textures? (To mother): Does he comment on your clothing?	1 = no interest in cloth or clothes 6 = constantly comments on and touches materials, calls mother's clothes pretty	I
	COMMENT	My son comments on his mother's clothing styles. . .	1 = never 3 = frequently	Q
Female peers	FRIENDS	Who is his best (next best) friend? Does he seem to prefer boys or girls as playmates?	1 = all male friends 5 = all female	I
	RELATE	My son relates best to . . .	1 = boys or adult males 2 = girls or adult females	Q
Rough play	SPORTS	My son's participation in sports is best described as . . .	1 = more than average 3 = less than average	Q
	RUFHS	My son's participation in the rough-and-tumble of boyhood is best described as . . .	1 = more than average 3 = less than average	Q
Be girl	BEGIRL	My son has stated his wish to be a girl . . .	1 = never 3 = frequently	Q

*$P<0.10$; **$P<0.05$; ***$P<0.01$

From 2 upwards there is more than incidental homosexuality, or bisexuality. Subjects were rated both for fantasy and interpersonal behaviour. Since the majority of our data were on boys in their teens (median age = 18), many of the boys were still sexually inactive with respect to interpersonal genital sexual behaviour. There are thus more ratings of sexual fantasy than of sexual behaviour.

Sexual fantasy ratings were derived by one of us from interviews discussing masturbation fantasies, nocturnal erotic dream imagery, and genital responsivity to pornography. The percentages of masturbation and dream fantasy content involving male or female partners, and the proportion of times erections would occur to homosexual or heterosexual pornography, were converted into appropriate placement on the seven-point scale (increments of approximately 14% for same-sex partners elevate the fantasy rating by 1 point).

Sexual behaviour ratings were derived from interview data regarding post-pubertal interpersonal genital experiences. Here, at least one same-sex experience results in a score above 0. As with the fantasy ratings, the proportion of experiences with male or female partners was converted into appropriate placement on the seven-point continuum (Green, 1985, 1987).

Data on boys' cross-gender behaviour, or 'femininity', derived from two identical questionnaires, designed and administered by one of us to each parent, and from three semi-structured audiotape recorded interviews (one with the couple one with each parent separately) by one of us that were transcribed and blind-coded. Questionnaires and interviews were administered prior to any therapy that a child or family may have had and that might have modified behaviour. Some interview items were asked again in different form on the questionnaires. Table I lists the 14 items rated; they fall roughly into five categories of cross-gender behaviour. Items are grouped here partially on the basis of content and partially on the basis of their inter-correlations.

Results

Regarding sexual fantasy, of the 44 males who were previously 'feminine' boys, eight had a Kinsey rating of 6 (exclusively homosexual), eleven had a rating of 5, seven a rating of 4, none a rating of 3, four a rating of 2, two a rating of 1, and twelve a rating of 0 (exclusively heterosexual). Thirty of this group also reported interpersonal sexual behaviour. Of these eight had a Kinsey rating of 6, six a rating of 5, seven a rating of 4, one a rating of 3, two a rating of 2, one a rating of 1, and five a rating of 0. The remaining 14 had not yet engaged in sufficient sexual behaviour to warrant a rating.

Of the 35 males who were previously 'masculine' boys, none had a Kinsey rating of sexual fantasy between 2 and 6 (bisexual to homosexual), and two had a rating of 1 (incidentally homosexual, but predominantly heterosexual). Of the 22 previously 'masculine' boys who reported interpersonal sexual behaviour, all had a rating of 0. The remaining 13 had not yet engaged in sufficient sexual behaviour to warrant a rating.

This high incidence of homosexual orientation among adolescents or young adults who displayed cross-gender behaviour in boyhood grants further legitimacy to the thesis that such types of behaviour are precursors of adult homosexuality.

Table II shows the correlations found between the cross-gender behaviour items listed in Table I. Correlations within each grouping of items are to the lower left hand side of the line. The fact that some correlations above this line are significant indicates the inter-relatedness of the types of cross-gender behaviour. For example, female role-playing and dress-up doll play often involve cross-dressing or an interest in feminine clothing. Desire to be a girl may be accompanied by cross-dressing and the ability to relate better to girls than to boys. However, the correlations within each of the five groupings in Table I are strong enough to permit their use as a basis for later generalisations.

Table III displays our principal findings: the zero-order correlations between the 14 measures of boyhood sex-typed behaviour and Kinsey sexual orientation ratings in adolescence and young adulthood within the 'feminine boy' group. The variables related to later sexual orientation are those items that fall into the role-playing and doll play category and the peer group cateogry. Doll playing has the strongest association of the three, and is related to sexual fantasy. Female role-playing tends to be related to both fantasy and behavioural ratings. Female peer group tends to be related only to fantasy, and then only when age at initial evaluation is controlled for. Cross-dressing is not associated with Kinsey ratings, and sexual orientation seems unrelated to the degree of rough-and-tumble play or sports, or the reported frequency of the stated desire to be a girl.

Some of the variables in Table III are associated with the boys' age at evaluation. For example, female role-playing, doll play, and cross-dressing are much less typical of a seven year-old than a four year-old. Futhermore, if a seven year-old cross-dresses, the chances are that he also cross-dressed at four. However, the reverse may not be as likely. Therefore, the zero order correlations were controlled for age at evaluation. To do this, a regression of variable X was run on age, and the residuals taken. The residuals are variable X adjusted for the linear effects of age. If we control the zero order correlations in Table III for age at evaluation, the correlations with role-playing and doll playing remain relatively unchanged. Thus, the associations do not appear to be a chance function of the age at which the boyhood measures were taken.

Discussion

Conclusions drawn from these data must be carefully qualified, taking into account the nature of the groups. Only boys who had atypical amounts of most of the five types of cross-gender behaviour were accepted for evaluation of the UCLA Gender Identity Clinic. Yet without taking into account variations in these boys' sex-typed behaviour, we know that the odds are about two to one that these boys would develop more than incidental homosexual fantasies in adolescence or young adulthood, and have more than incidental homosexual experiences.

Given that a boy does exhibit atypical amounts of cross-gender behaviour, the best predictors of later homosexual fantasies are, on the basis of our data, the degree to which he plays with dress-up dolls and (to a lesser extent) role-plays as a female or has females in his peer group. For later homosexual behaviour, the best predictor is role-playing as a female. Within the 'feminine boy' group cross-dressing is a poor predictor in this regard, as is the degree to which he participates in rough-and-tumble play or sports, and states the wish to be a girl. However, each behaviour is predictive of later sexual orientation, when comparing the two groups.

Since about half of transvestite males, who derive sexual arousal from dressing in women's clothes, begin cross-dressing prior to adolescence (Prince & Bentler, 1972), we predicted that some of the cross-dressing boys would become adult transvestites. Despite considerable cross-dressing among the boys, however, no one in our group developed transvestism. The reason for this may be the small probability of sampling a pre-transvestite, given the lower incidence of transvestism compared to homosexuality in the general population, and the small number of boys in our group. Transsexuals, too, report extensive childhood cross-gender behaviour (Benjamin, 1966). Despite a similarly low incidence of transsexualism in the general population, one of the previous 'feminine' boys, who is erotically attracted to males, also desires a sex-change operation (Green, 1987).

The development of adult sexual orientation appears most likely to involve interplay among a variety of intervening factors, such as innate features, relationship to parents, medical background, and parental concern over cross-gender behaviour (Green, 1987). Here we have only looked at a small portion of the developmental picture, but have found that a variety of types of boyhood behaviour appear characteristic of pre-homosexual males.

Comparing our two groups of males, several types of boyhood behaviour were more commonly found in the pre-homosexual or bisexual males. These included the frequently stated wish to be a girl, frequent cross-dressing, preferential role-playing as a female, a primarily female peer group, a preference for dress-up doll-play, an avoidance of rough-and-tumble play, and an avoidance of sports. However, within the 'feminine' boy group, it was primarily role-playing as a female, playing with dress-up dolls, and a female peer group that were associated with later ratings of sexual orientation. Here, the more these types of behaviour were engaged in, the higher (more homosexual) was the later rating of sexual orientation.

CSF Monoamines in Autistic Syndromes and Other Pervasive Developmental Disorders of Early Childhood

C. GILLBERG and L. SVENNERHOLM

Spinal fluid concentrations of the three major monoamine metabolites were examined in 25 infantile autistic children and 12 children with other childhood psychoses, and were contrasted with results obtained in normal children and in groups of children with neurological and neurodevelopmental disorders. Autistic children showed absolute and relative increases of the dopamine metabolite homovanillic acid. The group with other childhood psychoses also showed an increase in HVA level; in this group there were also indications of high levels of serotonin and norepinephrine metabolites. The results are discussed in the context of a pathogenetic model for autism involving hyperfunction of dopaminergic nerve fibres in the brain stem-mesolimbic system.

Infantile autism – as defined by DSM–III (American Psychiatric Association, 1980) – and the other childhood psychoses are currently thought to be caused by hereditary factors or brain damage, singly or in combination (Folstein & Rutter, 1977; Ornitz, 1983; Coleman & Gillberg, 1985). Biochemical dysfunction is likely to be of importance, and several early studies on peripheral blood have indicated hyperfunction of serotonin (Hanley *et al*, 1977; Ritvo *et al*, 1970). Later studies have indicated hyperfunction of dopamine, as judged by measurements of homovanillic acid (HVA) and endorphin in the cerebrospinal fluid (CSF) (Winsberg *et al*, 1980; Gillberg *et al*, 1983; Gillberg *et al*, 1985). We recently reported preliminary findings of raised HVA levels in the CSF of 13 autistic children (Gillberg *et al*, 1983). We now present results of CSF monoamine analyses on 37 psychotic children, 25 of whom were diagnosed as suffering from infantile autism.

Subjects

Infantile autism

Twenty-five children (20 boys and 5 girls) diagnosed by an experienced child psychiatrist as suffering from infantile autism (IA) were included in the study. They were consecutive autistic patients at a university clinic of child psychiatry in Western Sweden, where the majority of autistic children in that part of the country are assessed. All cases had: (a) early onset (before 30 months of age); (b) severe disturbance of social relatedness, involving lack of reciprocity and a period in infancy of autistic aloneness; (c) severe disturbance of language, expressed as muteness or echolalia with reversal of pronouns, plus impaired comprehension of mime, gesture and spoken language; and (d) severe behaviour disturbances involving insistence on sameness, development of elaborate repetitive routines, and odd play behaviour. All the children, who ranged in age from 1–16 years of age (mean = 8.1, s.d. = 4.3), fulfilled DSM–III and Rutter's (1978) criteria for infantile autism and fitted the clinical picture outlined by Kanner & Eisenberg (1956).

A number of the autistic children showed additional handicaps, such as mental retardation or epilepsy (Table I), and two children were on medication (clomipramine) at the time of the study.

Other childhood psychoses

Twelve children (8 boys and 4 girls) fulfilled DSM–III criteria for childhood onset pervasive developmental disorder; i.e. they showed many of the symptoms typical of autism, but the age of onset could not be objectively proven using medical record data to be prior to 30 months (which does not preclude the possibility of early symptoms). These children will be referred to as suffering from 'other childhood psychoses' (OP). Some of the children in this group also were multiply handicapped, but only two (both girls) were on any kind of medication (one on valproate and one on carbamazepine). The age range in this group was 3–13 years (mean = 8.3, s.d. = 3.3).

Control groups

The control group for IA consisted of 20 children (15 boys and 5 girls), matched for sex and age (within one year, or two months for two children aged under four) with the first 20 of the 25 autistic children. The mean age at examination in this group was 8.3 years (s.d. = 4.3).

The control group for OP consisted of 10 children (6 boys and 4 girls) matched for sex and age (within two years) with the first 10 of the 12 children with other childhood psychoses. (The psychotic children under four years were matched for age with children who were two months younger.) The age range in this group was 3–13 years (mean = 10.0, s.d. = 3.5).

TABLE I
Characteristics of the IA and OP groups of children

Group	*Case no.*	*Sex*	*Age: years*	*IQ*	*Epilepsy*	*Other major handicap/abnormality*[1]

1. Results of computerised tomography scans and neurochemical tests not included.
2. Chromosomal culture in folic-acid-depleted medium.
3. According to examination of auditory brain stem responses.
4. According to EEG in the waking state.

All the children in these control groups had had a lumbar puncture because a disorder affecting the central nervous system (febrile virosis, pneumonia or otitis with meningismus ($n=16$), syncope ($n=2$), Bell's palsy ($n=1$), retinal degeneration ($n=1$), headache ($n=3$), paraesthesia, hysteria? ($n=1$), obsessions ($n=1$), tics ($n=1$), and other transient neurological problems ($n=4$)) had been suspected; these disorders were later ruled out. None of the children in these groups were on medication when their CSF samples were taken.

Mental retardation group

A group consisting of 10 non-autistic, non-psychotic mentally retarded (MR) children, aged 3–14 years (mean = 8.0, s.d. = 2.7) were also examined. Four of these also had cerebral palsy (CP), and one child had the combination of MR, CP and epilepsy. The epileptic child was on phenytoin; no other children were on medication at the time of the study.

Progressive encephalopathy group

Five children (3 boys and 2 girls) with severe mental retardation and unequivocal signs of deterioration were referred to the progressive encephalopathy group. They were without psychotic symptoms. The age range was 4–13 years (mean = 9.2, s.d. = 4.3). None of these children were receiving drugs.

Meningitis group

Seven children (4 boys and 3 girls) were referred to the meningitis group; CSF specimens for monoamine analysis were obtained in the acute febrile state of the disease before any kind of treatment had been started. The causative agents were Haemophilus influenza in one case and possibly viral in the remaining six cases. The age range in this group was 2–16 years (mean = 7.6, s.d. = 4.7).

Method

Lumbar puncture/CSF collection

Lumbar punctures were performed under local anaesthesia. All children in the study and the comparison groups had been allowed to move about freely before the lumbar puncture, and there had been no other restriction. Two children in the IA comparison group had been confined to bed because of a virus infection and pyrexia. No premedication was given. The first 3 ml of CSF was collected from all children in the study, and was kept frozen until the monoamine analysis was made.

The lumbar punctures were performed by the same child psychiatrist in 30 of the 37 cases with psychosis, because he was well known to the children and doctors not well acquainted with the problem of psychosis in childhood often feel uneasy in such situations. In the majority of the cases with psychosis the child was also accompanied by a therapist or teacher whom they knew well, who would sit by the child's side and talk or sing to him or her during the procedure. The majority of the lumbar punctures were performed in the afternoon, especially in the psychosis group and their comparison groups. Some of the punctures (e.g. those done on acute indication) were performed at other times.

Determination of monoamine metabolites

Mass fragmentographic determination of HVA and 5-hydroxyindole-acetic acid (5-HIAA) was performed on 0.2 ml samples of CSF in a procedure modified from that described by Swahn *et al* (1976). To each sample of CSF, 0.4 nmol of deuterated HVA and 0.2 nmol of deuterated 5-HIAA were added as internal standards. The pH of the sample was adjusted to about 2 with formic acid, and after saturation with sodium chloride the metabolites were extracted with two portions of diethyl ether (0.5 ml). The solvent was evaporated under nitrogen, and the pentafluoropropionyl derivatives were prepared by the addition of 20% pentafluoropropanol in pentafluoropropionic anhydride (50 µl) and heating to 75°C in a sealed tube. The process of forming derivatives was repeated once; the sample was then evaporated to dryness *in vacuo* and finally dissolved in ethyl acetate (25 µl). About 5 µl of the solution was used for the analysis.

Hydroxymethoxyphenylglycol (HMPG) was assayed on a second sample of 0.2 ml CSF. After the addition of deuterated HMPG (0.1 nmol) and saturation with sodium chloride, the sample was extracted with two portions of ethyl acetate (0.5 ml) instead of diethyl ether. After evaporation, a trifluoro-derivative was made by the reaction of the sample dissolved in ethyl acetate (25 µl) with trifluoroacetic anhydride (25 µl) for one hour at room temperature. All determinations were done in duplicate on a LKB 2091 gas chromatograph/mass spectrometer. The recovery of the three metabolites varied between 75% and 90%, and the coefficient of variation, determined from duplicate analyses, between 3.6% for HVA and 6.8% for 5-HIAA.

Results

Infantile autism group

Mean CSF HVA concentrations were significantly higher in the autism group than in the IA control group ($P < 0.001$); 18 of the 20 control group children had lower HVA concentrations than their corresponding autism proband. 5-HIAA and HMPG concentrations did not differ significantly between the two groups (Table II).

The concentrations of HVA and 5-HIAA relative to that

	Other childhood psychosis group ($n=12$): nmol/l		*Control group ($n=10$): nmol/l*	
	Mean	*s.d.*	*Mean*	*s.d.*
HVA	513*	219	263*	174
5-HIAA	148	57	103	46
HMPG	73**	12	61**	8

*$P<0.01$; **$P<0.05$.

of HMPG, which showed the least variation of the metabolites in all the study groups, are shown in Table III and Fig. 1. Not only is HVA raised in the autistic group, but the relative excess of this metabolite as compared with 5-HIAA is marked. The IA control group appears to consist of 2 subgroups: one (labelled (a) in Fig. 1) with an almost linear relationship between the three metabolites, and another (labelled (b) in Fig. 1) with a more conspicuous discrepancy between relative HVA and 5-HIAA concentrations. At least two of the seven cases in subgroup (b) had psychiatric problems. It might be that subgroup (a) is in fact the 'normal' comparison group.

The mean HVA:HMPG ratio was significantly higher in the autism than in the IA control group ($P<0.001$). No difference between the groups emerged in respect of 5-HIAA:HMPG ratios.

Other psychosis group

Mean CSF HVA concentrations were raised in the OP group compared with the OP control group ($P<0.01$) (Table IV, Fig. 2). Eight of the 10 OP control group children had lower HVA concentrations than their corresponding psychotic probands. CSF 5-HIAA and HMPG concentrations tended to be higher in the psychotic group, but the differences fell just short of statistical significance in respect of 5-HIAA.

Other groups

The HVA concentrations in the MR group (mean = 271, s.d. = 109 nmol/l) were close to those of the control groups, but 5-HIAA and HMPG levels were slightly higher (mean = 130, s.d. = 59 nmol/l and mean = 80, s.d. = 50 nmol/l respectively). The HVA and 5-HIAA concentrations were much higher in the progressive encephalopathy group than in the control groups (mean = 605, s.d. = 114 nmol/l and mean = 276, s.d. = 116 nmol/l respectively). There was no difference with regard to HMPG concentration (mean = 70, s.d. = 9 nmol/l). In the meningitis group the mean HVA concentration was almost as high as in the progressive encephalopathy group, but there was considerable individual variation (mean = 598, s.d. = 366 nmol/l). The 5-HIAA concentration was also raised, compared with the control group (mean = 167, s.d. = 64 nmol/l), but the HMPG concentration was in the normal range (mean = 75, s.d. = 14 nmol/l).

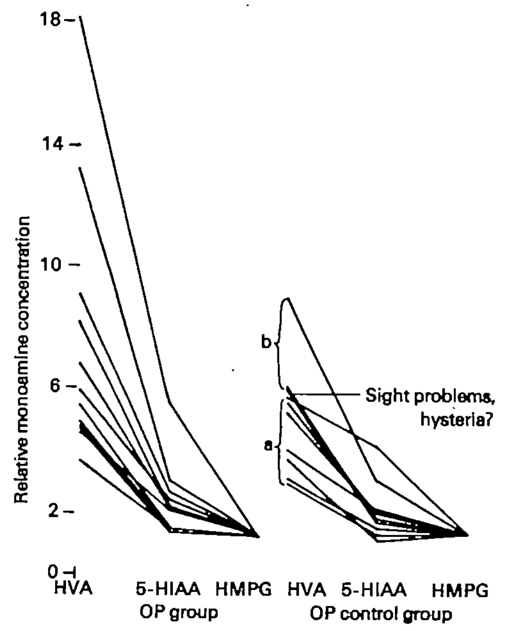

FIG. 2. HVA and 5-HIAA concentrations in the OP and control groups, relative to HMPG concentration.

Age, IQ and sex correlations with monoamine concentrations In all the study groups there were clear-cut age trends; monoamine concentrations generally declined with increasing age of the child (Table V). This appeared to hold true especially if the children were under the age of five or if they were of short stature for other reasons.

IQ did not correlate in any meaningful way with HVA concentrations, either in the autism group, or in the group with other childhood psychoses. However, it appeared that in the autism group high levels of 5-HIAA correlated with low IQ ($r = -0.45$, $P < 0.05$).

TABLE V

Pearson product-moment correlation between age and monoamine concentrations in the IA, OP and control groups

Group	*HVA*	*5-HIAA*	*HMPG*
IA ($n=25$)	−0.56**	−0.66**	−0.07
IA control ($n=20$)	−0.62**	−0.74**	−0.47*
OP ($n=12$)	−0.58*	−0.63*	−0.16
OP control ($n=10$)	−0.85**	−0.64*	−0.34

*$P < 0.05$; **$P < 0.01$.

The girls tended to show slightly lower monoamine CSF-concentrations than the boys. However, all differences were statistically insignificant. Since there were relatively few girls the results are not conclusive. Furthermore, the girls were somewhat older than the boys, and the differences might be accounted for by age effects.

Discussion

We have previously presented preliminary evidence indicating dopamine hyperfunction in the CSF of autistic children (Gillberg *et al*, 1983). This new extended study on 25 autistic children and 12 children with other psychoses of early childhood adds further support for the hypothesis (Maurer & Damasio, 1982; Coleman & Gillberg, 1985) that dysfunction of CNS dopaminergic pathways might be important in autism and autistic-like conditions.

However, several things must be borne in mind. Firstly, although in this context the group was fairly large, the number of autistic children included was too small for firm conclusions to be drawn. The number of children in the other psychosis group (and its control group) was much too small for the results in that group to serve as anything other than a basis for tentative suggestions.

Secondly, the control groups of children did not consist of perfectly healthy children, although a majority of them were free of psychiatric disorders. This means that we have not provided hard proof that levels of HVA in CSF are really higher in autistic or psychotic children than in normal children. However, we consider our control groups acceptable, and feel that ethical considerations would preclude a CSF study on children without even any kind of acute ailment.

Thirdly, high dopamine levels should not be taken as ultimate proof of primary central nervous system dysfunction. However, studies by Sedvall *et al* (1980) on adults provide support for the notion that altered monoamine metabolism in the CSF indicates primary central nervous system vulnerability.

Finally, one might argue that factors not intrinsic to the psychotic disorder (e.g. food, drink, or activity level) might cause the deviant results. We found no such meaningful correlation, but some factors may have been missed.

It appeared that isolated elevation of dopamine was typical of autism, and that in the other psychosis group all three metabolites tended to be raised. Several studies have shown that about one-third of 'autistic' children have raised levels of blood serotonin. The tendency found in our study towards high CSF 5-HIAA levels in the other psychosis group is therefore of some interest. However, in our autistic subjects high CSF 5-HIAA levels correlated significantly with mental retardation but not with autism. This might mean that hyperfunction of 5-HIAA in the field of childhood psychosis is a non-specific finding linked with the IQ rather than with the psychiatric abnormality of the child. This line of reasoning has been supported by a number of authors (see Young *et al*, 1982; Coleman & Gillberg, 1985).

There was no indication in the present study that the high HVA levels could be accounted for by mental retardation. In the autistic group, high HVA levels correlated with autism and not with low IQ. Furthermore, the mentally retarded group without autistic features showed results compatible with those of the normal control groups.

High monoamine metabolite levels in the CSF showed an inverse relationship with age both in the psychosis and the control groups. There was no suggestion that the age trend could explain the difference between index and control cases. Nevertheless, 'immaturity' of the nervous system in the psychotic children might turn out to be one important factor, even though the results in the small mental retardation group tended to contradict such an interpretation.

A number of authors (Young *et al*, 1982; Maurer & Damasio, 1982; Coleman & Gillberg, 1985) have hypothesised – on the basis of animal research, results from adult psychiatry and simple case studies of autistic syndromes in childhood – that hyperfunction of dopaminergic pathways arising in the brain-stem and projecting rostrally to mesolimbic structures in the temporal and frontal lobes might be crucial in the pathogenesis of certain symptoms in autism. Coleman & Gillberg (1985) have proposed a theory implicating bilateral mesolimbic dysfunction or damage as essential in producing the core symptoms (incomprehension of human mime and gesture, inability to relate reciprocally to other people) in infantile autism. Mesolimbic areas might be dysfunctional *sui generis*, but may also be dysfunctional because of lack of input from the brain-stem, which in turn might be caused either by primary brain-stem damage (leading to denervation hyperfunction of the dopaminergic pathways connecting the brain-stem with the mesolimbic structure) or by primary dysfunction of the dopaminergic nerve fibres. We found evidence of brain-stem dysfunction in 28% of our autistic group (and in none of the other psychosis group) and of bilateral temperal lobe dysfunction in 12% (8% in the other psychosis group).

It is unclear whether there exist real differences in respect of CSF monoamine contents between children with autism and those with other childhood psychoses. Our results indicated specific dysfunction of dopamine in autism and non-specific elevation of all the studied metabolites in the other psychosis category, but further studies are needed before any well-founded hypotheses can be proposed. The ratio of HVA:5-HIAA:HMPG might prove to be more important than absolute values for these metabolites. For instance, the HVA:HMPG ratio was greater than 6 in 64% of the autism cases, in 44% of the other psychosis cases (in spite of the fact that this group showed the highest absolute values), and in 15% and 10% respectively of cases in the comparison groups.

Relationship between Interictal Psychopathology and the Type of Epilepsy

Results of a Survey in General Practice

J. EDEH and B. TOONE

Psychiatric morbidity was assessed in a sample of 88 adult epileptic patients drawn from general practices in South London. Using the Clinical Interview Schedule, 48% emerged as psychiatric cases. When either total CIS score or caseness status was used for comparison, group differences were evident; patients with temporal lobe epilepsy and focal non-TLE did not differ, but each was significantly more impaired than those with primary generalised epilepsy. The groups also differed in their psychiatric symptom profiles. The results suggest that the increased prevalence of interictal psychopathology commonly associated with TLE may also be a feature of other forms of focal epilepsy.

Much has been written on the nature of psychiatric illness in epilepsy, and few would dispute that there appears to be a substantial increase in psychiatric morbidity among epileptic patients. However, our understanding of this subject has been formed by studies of patients in the settings of hospital, institution, or clinic. Although often of high quality, these offer a limited perspective of a highly selected clinical population and one moreover that is selected for, among other factors, vulnerability to psychiatric illness. Prevalence measures derived from such unrepresentative samples may therefore seriously overestimate psychiatric morbidity among epileptic patients. Other issues may also be obscured: one that remains a source of controversy is the alleged vulnerability of patients with temporal lobe epilepsy (TLE) to psychiatric illness.

The central role of the limbic system in the integration and expression of emotional experience has long been recognised (Papez, 1937; Yakovlev, 1948; McLean, 1970) and the increased prevalence of psychiatric disorder among epileptic patients is also well established (Pond & Bidwell, 1959; Gudmundsson, 1966; Rutter *et al*, 1970). The early observation of an association between anterior temporal lobe foci and the presence of major psychiatric illness (Gibbs *et al*, 1948) was therefore not unexpected, and was in accordance with common clinical experience. Further studies (Pond & Bidwell, 1959; Currie *et al*, 1971) have given evidence of an unusually high prevalence of psychiatric disorder in patients with TLE, while an association has also been reported with more specific behavioural syndromes and disabilities, e.g. sexual deviation (Kolarsky *et al*, 1967), personality disorder (Bear & Fedio, 1977), and psychosis (Slater *et al*, 1963). However, a number of studies (Small *et al*, 1962; Stevens, 1966; Standage & Fenton, 1975) have reported essentially negative findings, so that the issue remains controversial and unresolved.

Methodological shortcomings may explain some of these discrepancies. In early studies in particular, diagnostic criteria for both epilepsy and psychiatric disorder were ill-defined, and as a consequence major inconsistencies in the reported prevalence of different disorders are not infrequent, e.g. psychosis in TLE (Ervin *et al*, 1955; Stevens, 1966). The choice of investigatory techniques has also been criticised (Bear & Fedio, 1977). Questionnaires such as the Minnesota Multiphasic Personality Inventory, standardised against an unselected population and designed to measure trait rather than state, may be too insensitive to elicit the more specific personality characteristics observed in TLE and ill-fitted to record current mental state.

However, the choice of unrepresentive patient samples remains the most likely source of error (Stevens, 1966). Poor treatment response in newly referred patients is associated with the presence of complex partial seizures and with neuropsychiatric findings (Reynolds *et al*, 1983); such patients are less likely to be referred back to their general practitioners for continuing care and will in time come to make up the greater number of clinic attenders (Edeh, 1984). Epidemiological findings support this view (Gastaut *et al*, 1975; Hauser & Kurland, 1975).

Any attempt to compare temporal lobe and non-temporal lobe epileptics with respect to psychiatric morbidity will therefore be prone to sampling error.

These biases can best be avoided by a comprehensive survey of a population of unselected epileptic patients in the community, but regrettably there has been little published work in this area. Pond & Bidwell's (1959) study of 14 general practices appears in retrospect a landmark that has not yet been repeated. Excellent though this study was, the availability of investigatory facilities was then limited and specialist opinion not always sought. The criteria for diagnosis of epilepsy subtypes would not satisfy present-day requirements, while instruments for measurement of psychiatric morbidity in a community were not yet available. The latter was expressed in terms of the proportion of patients who had sought or received psychiatric treatment – the "conspicuous morbidity" (Kessel, 1960). The aim of the present study was to estimate both the conspicuous and hidden morbidity in an unselected general practice-based population. Application of rigorous diagnostic criteria for temporal lobe and non-temporal epilepsy should permit a comparison of these epileptic sub-categories in terms of psychiatric disturbance.

Method

We examined the prescribing arrangements of 14 general practitioners working in five group practices in South London (Lambeth, Croydon, and Bromley); 103 patients (aged 16 years and over) out of a total registered adult population of 29 822 (prevalence rate 3.45/1000) regularly received repeat prescriptions of anticonvulsant medication. All satisfied the operational criteria for the definition of epilepsy of Gunn & Fenton (1969): "a history of at least three epileptic attacks in any two-year period and the continuation of anticonvulsant therapy, if the period did not immediately precede the time of examination".

Eighty-eight of the sample agreed to participate in the survey. All practice records were scrutinised for information regarding history of epilepsy, previous investigations, and current treatment, while further information on 79 patients was obtained from hospital casenotes. Each patient was seen at home in the evening for psychiatric assessment using the Clinical Interview Schedule (CIS) (Goldberg *et al*, 1970), and was subsequently invited to attend hospital for clinical investigations; these were carried out at the Maudsley Hospital within 7–14 days of the interview. The home visits and clinical investigations were completed in 15 months.

Psychiatric morbidity

Psychiatric ratings on the CIS were derived from ten symptoms commonly reported in general practice and from 12 manifest abnormalities observed by the psychiatrist. Each of the 22 ratings were made on a five-point scale: O for normal; 1 for sub-clinical disturbance or trait; and 2, 3 and 4 for mild, moderate, or severe clinical disturbance respectively. As recommended by Goldberg, a total CIS score was calculated for each patient by adding together the ratings for all ten reported symptoms and double the ratings for all 12 manifest abnormalities.

A patient scoring 13 or more was classed as a case (Benjamin *et al*, 1982; Hobbs *et al*, 1983). Each case received a clinical diagnosis according to ICD-9 (World Health Organization, 1978).

Social correlates of psychiatric disorder were assessed using the Schedule for Social Maladjustment and Dysfunction (Clare & Cairns, 1978); this will be the subject of a separate paper.

EEG and CT scans

A 16 channel electroencephalographic (EEG) recording was carried out on all patients, using the 10–20 international system of electrode placement. All records were assessed by established methods of visual interpretation by a consultant clinical neurophysiologist. Computerised tomography (CT) was carried out using an EMI CT 1010 Head Scanner; enhancement, when indicated, was achieved with intravenous iodinated contrast medium (sodium iothalamate – Conray 420, 1 ml/kg body weight). The CT scan films were assessed independently by a consultant neuroradiologist.

Diagnosis and classification of epilepsy

The type of epilepsy was diagnosed on combined clinical and EEG considerations (Gastaut, 1969; Parsonage, 1983). Patients with primary generalised epilepsy (PGE) lacked a preceding aura, localising event during or after the seizure, a history of cerebral insult, or focal neurological signs; EEG was normal or showed generalised spike, polyspike, or spike-wave complexes with bilateral distribution and without a sharp or slow wave focus.

Partial epilepsies were differentiated by the presence of an initial event of localising significance and an EEG spike, sharp or slow wave focus. Patients with TLE presented features of complex partial seizures or abnormal interictal EEG records showing spike, sharp, or slow wave focus, and phase-reversal over the anterior or mid-temporal areas (Ervin, 1967; Driver, 1970).

Coding and statistical analysis

All the survey data were entered into coded questionnaires and punched onto cards, which were verified for punching errors. Analysis was subsequently carried out on the University of London's AMDAHL 470/v8 computer, accessed through the King's College Hospital Medical School terminal system. Significant differences across the epilepsy sub-categories were determined using the Kruskal-Wallis one-way analysis of variance (ANOVA) (Siegel, 1956); comparison between groups used the Mann-Whitney U test or the chi-squared test as indicated.

TABLE I

Characteristics of the epilepsy sub-categories

	PGE *(n=41)*	*Focal non-TLE* *(n=22)*	*TLE* *(n=25)*

Abnormal*	9 (22%)	13 (59%)	11 (44%)

*$\chi^2 = 6.78$ ($P<0.01$) for differences between PGE and focal non-TLE.

Results

Patients were grouped into three epilepsy sub-categories: TLE ($n=25$), focal non-TLE ($n=22$) and PGE ($n=41$) according to the criteria described above. Fifteen patients refused to participate in the study, or agreed to be interviewed but failed to attend for hospital investigations. According to their casenotes, six would appear to have PGE and six partial epilepsy. Seven had a history of psychiatric illness (four cases with neuroses, and one each with personality disorder, periodic psychotic episodes, and mental subnormality); thus, they did not seem to differ markedly from those in the study.

Characteristics of the groups

The results are summarised in Table I. The male female sex ratio was approximately the same for all three groups. Mean age, age of seizure onset, and duration of epilepsy were broadly similar. Control of seizure was better in patients with PGE compared with either those with focal non-TLE or TLE, but the difference did not reach statistical significance. More patients with PGE were on a single anticonvulsant drug, compared with those with TLE and focal non-TLE.

In the PGE group 22% of the patients had abnormal CT scan, compared with 59% of those with focal non-TLE; this difference is significant ($\chi^2=6.78$, $P<0.01$), but comparison of CT scan abnormalities between patients with PGE and TLE or between focal non-TLE and TLE did not reveal a significant difference.

History of previous psychiatric referral

Twenty-seven patients (31%) had a history of psychiatric

TABLE II

Comparison of the epilepsy sub-categories on the CIS items

CIS items	*ANOVA** *H*	*P*	*Inter-group*** *differences*
Reported symptoms			
Irritability	5.644	0.05	PGE vs TLE; $P<0.02$ PGE vs focal non-TLE; $P<0.01$
Impaired concentration	9.854	0.007	PGE vs TLE; $P<0.01$
Depression	6.314	0.043	PGE vs TLE; $P<0.02$
Anxiety	5.715	0.05	TLE vs focal non-TLE; $P<0.02$
Manifest abnormalities			
Depressed affect	6.815	0.03	PGE vs TLE; $P<0.02$ TLE vs focal non-TLE; $P<0.05$
Intellectual impairment	7.652	0.02	PGE vs focal non-TLE; $P<0.01$

**Mann-Whitney U test.

referral – six with PGE, ten with focal non-TLE, and eleven with TLE ($\chi^2 = 4.83$, NS). The difference between focal epilepsy (TLE and non-TLE) and PGE was significant ($\chi^2 = 7.94$, d.f. = 1, $P < 0.01$).

Psychiatric symptom profile

Statistical analysis was performed on the CIS ratings in two stages: the Kruskal-Wallis one-way analysis of variance was applied across the groups, and where a significant difference was observed at the one in twenty level significance, further analysis was carried out using the Mann-Whitney U test to determine differences between groups.

Difference across groups (Table II). Significant differences across groups were demonstrated for mean ratings on irritability, depression, anxiety and impaired concentration; among manifest abnomalities, depressed affect and intellectual impairment had significant differences.

Other CIS items rated under reported symptoms (somatic, fatigue, sleep disturbance, phobias, obsessions and depersonalisation)and under manifest abnormalities (spontaneity, suspiciousness, histrionic behaviour, anxiety, elated or flat affect, delusions, hallucinations, excessive concern with bodily functions, and depressed thoughts) failed to show any significant difference across the epilepsy sub-categories.

Difference between groups. On the reported symptoms the TLE group rated more highly on anxiety than the focal non-TLE group and more highly on irritability, depression and impaired concentration than the PGE group.

On manifest abnormalities the TLE group scored more heavily on depressed affect than either the PGE or focal non-TLE groups. The focal non-TLE group was more intellectually impaired than the PGE group at the one in one hundred level.

Severity of psychiatric disturbance

Figure 1 shows the distribution of the total CIS scores for the three epilepsy sub-categories. Differences between patients with focal non-TLE and TLE were not significant, but the differences between those with PGE and TLE, and between those with PGE and focal non-TLE were statistically significant at the one in twenty level.

The proportion of patients regarded as normal (rating 0) and those with varying degrees of psychiatric disturbance (ratings 1–4) did not differ between the groups with partial epilepsy, but significant differences were observed between PGE and focal non-TLE and between PGE and TLE (Table III).

Diagnostic categories

Psychiatric diagnosis according to epilepsy subtypes is shown in Table IV. The majority of patients who received a psychiatric diagnosis were thought to be either cases of anxiety or depressive neuroses. Other diagnostic categories made up less than 24% of the psychiatric cases, or less than 15% of the whole sample. Anxiety neurosis was evenly distributed among the epilepsy sub-categories, but there were more patients with depressive neurosis in the TLE group compared with those with focal non-TLE and PGE.

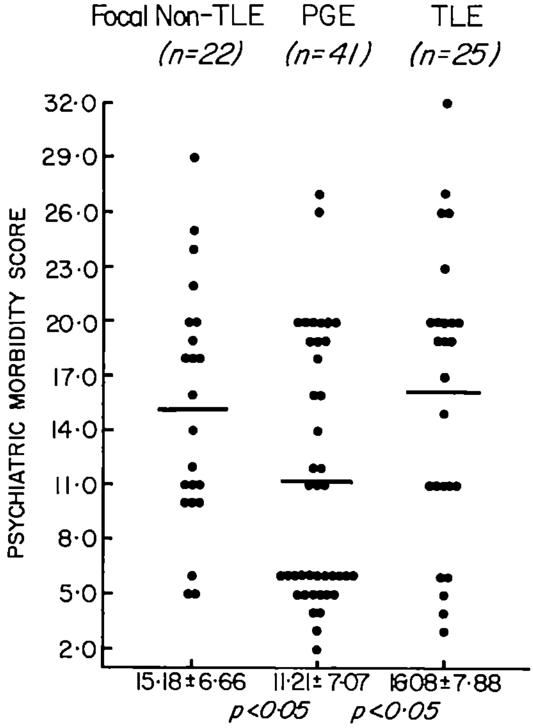

FIG. 1 Distribution of total CIS scores for the epilepsy sub-categories. Means and standard deviations are given at the base of each column, and the means are also indicated by a rule on the graph.

Discussion

The high prevalence of psychiatric morbidity in epilepsy has been frequently reported; although Pond & Bidwell (1959) reported a prevalence of 29% in general practice, Pond (1981) criticised this figure as an underestimate. It represents only conspicuous psychiatric morbidity (Kessel, 1960), and is consistent with the proportion of cases in the current survey (30.7%) known to have had previous out-patient psychiatric referral. With the use of the CIS, 42 (47.7%) of the sample emerged as 'cases', and according to clinical diagnosis, three-quarters had some form of affective neurosis.

The assertion (Gibbs, 1951) that TLE is more associated with increased psychiatric morbidity than other forms of epilepsy provoked a controversy that has persisted until the present day. It is possible to attribute at least some of this disagreement to methodological shortcomings. In particular, the

TABLE III
Type of epilepsy and severity of psychiatric disturbance

	*Severity of psychiatric disturbance**	*PGE (n=41)*	*Focal non-TLE (n=22)*	*TLE (n=25)*	*Total*
0	Normal	21 (51%)	3 (14%)	5 (20%)	29
1	Sub-clinical	5 (12%)	7 (32%)	5 (20%)	17
2	Mild	13 (32%)	8 (36%)	10 (40%)	31
3	Moderate	2 (5%)	3 (14%)	4 (16%)	9
4	Severe	0	1 (4%)	1 (4%)	2

*The following comparisons were made of the size of the normal group compared with the size of the group comprising severities 1–4: PGE versus focal non-TLE ($\chi^2=7.05$, $P<0.01$); PGE versus TLE ($\chi^2=5.10$; $P<0.05$); focal non-TLE versus TLE (NS) (Fisher's exact test).

great majority of studies have reported on hospital-based epileptic populations, but it has become increasingly apparent that such samples are unrepresentative. This observation is borne out by data from our own study: partial epilepsy with complex seizures was significantly over-represented among hospital clinic patients compared with clinic non-attenders (i.e. patients managed by general practitioners) (Edeh, 1984). Psychiatric morbidity, using either CIS scores or caseness as criteria, was greater in the first group, and we have attempted to avoid this error by studying an unselected community population.

Nevertheless, there are limitations in the study design. Unlike the survey of 14 general practices (Pond & Bidwell, 1959; Pond *et al*, 1960) which sampled over a wide area and from both urban and rural districts, this study was limited to South London; a wider spread would have been desirable, but was not possible for administrative reasons. Even so, a balance between inner-city (Brixton) and outer suburbs (Beckenham and Croydon) was achieved which seems fairly representative of the metropolitan population. The point-prevalence (3.45/1000) is comparable with other studies that used similar inclusion criteria (Kurland, 1959; Gudmundsson, 1966; Hopkins & Scambler, 1977), and suggests that ascertainment was reasonably complete. The clinical characteristics, in so far as they could be determined, of the minority of patients who refused to co-operate with our survey did not clearly differ from those studied.

The methodology of clinical assessment has also generated controversy. Criticism has been levelled at the use of instruments that fail to distinguish between state and trait and between the evaluation of abnormal mental states and the assessment of personality structure. In this study the emphasis was on clinical assessment, and the CIS was chosen because it combines a careful but unstructured enquiry into the patient's past history with a detailed and systematic assessment of current symptomatology and mental state.

The findings suggest a greater prevalence of psychiatric morbidity in the focal group, especially those with temporal lobe foci, than in the PGE group. This is so when comparison is based on an unstructured account of past and present psychiatric illness, and also when current symptoms and manifest abnormalities are compared. The TLE group was rated more highly than the focal non-TLE lobe group on measures of anxiety and depressed affect and more than the PGE group on irritability, depression, depressed affect, and impaired concentration. In terms of global severity of psychiatric disturbance, the focal groups did not differ; each scored more highly than the PGE group.

How may the increased psychopathology in the temporal lobe group be explained? Structural brain damage, as demonstrated by abnormal CT scan appearances, was common in the focal epileptic groups (there was, across the groups, an insignificant trend towards increased psychiatric morbidity among patients with CT scan abnormalities); seizure control was poorer. In neither instance were the comparisons between the TLE and PGE groups significant.

There have been few community studies of psychiatric morbidity in epilepsy, and our findings are not easily compared with those of Pond & Bidwell (1959), the other British study. Their choice of broad inclusion criteria resulted in prevalence figures that were unusually high (6.2/1000, almost twice that of the present study). Only 39 of 245 patients (an unexpectedly small proportion) were thought to have TLE, and these mainly on clinical grounds, as few had had EEGs; 20 were thought to have "serious psychological disorders", but only 11 showed the "typical slowness, stickiness, moodiness and psychotic tendencies that constitute the so called epileptic personality". Eight (20%) had already been in mental hospitals, compared with 7% for the group as a whole – a figure itself considerably higher than in the general population.

Our study did not employ specific measures of personality structure, such as had been designed by Bear & Fedio (1977), who claimed that "a consistent change in behaviour, thought and affect appeared to be the specific consequence of a temporal epileptic focus". That assertion, then supported only by a comparison of temporal lobe epileptics with a group of patients with peripheral neurological disturbance, would appear premature. Other workers (Masters *et al*, 1984) comparing temporal lobe with other forms of epilepsy, psychiatric illness, and normal control groups failed to detect trait characteristics of the temporal lobe group. In the present study, two patients were thought to have personality disorders; both were diagnosed as having PGE.

The majority of 'cases' were thought to have a minor affective disturbance, usually of an anxious or depressive nature; this is in line with other recent published work from this country (Standage & Fenton, 1975; Robertson & Trimble, 1983). Earlier American studies gave greater prominence to psychosis (Ervin *et al*, 1955; Stevens, 1966) – a discrepancy partly explained by international variations in selection and case-finding criteria.

Our findings suggest, therefore, rather than a distinction between temporal lobe and non-temporal lobe epilepsy, a separation between focal epilepsy, regardless of site of focus, and PGE. With respect to the percentage of subjects who had received psychiatric treatment and to the global psychiatric morbidity scores, the two focal groups fared similarly. The reasons for the differences between focal and primary generalised epilepsy are not clear. The presence of brain damage, implicit in the diagnosis of focal epilepsy and further demonstrated by CT scanning, the relatively poor seizure control, and even the wider prescription of drugs, may each be regarded as a stress factor, insignificant in isolation but exerting a cumulative effect. Rodin *et al* (1976) have suggested a multifactorial explanation for the behavioural change in patients with TLE, particularly the high prevalence of multiple drug prescription and multiple seizures: these data provide qualified support for their view.

Response of Depressive Symptoms to Nortriptyline, Phenelzine and Placebo

ANASTASIOS GEORGOTAS, ROBERT E. McCUE, EITAN FRIEDMAN and THOMAS B. COOPER

The effects of nortriptyline, phenelzine, and placebo on 13 symptoms of depression were compared in 75 patients, aged 55 or over, who were suffering from major depression. Nortriptyline and phenelzine were more effective than placebo in treating depression mood, guilt feelings, suicidal ideation, agitation, anxiety, loss of energy, and a.m. diurnal variation of mood. Nortriptyline was better than phenelzine or placebo in improving middle/late insomnia. Most of the symptoms did not show significant improvement until the fourth week of treatment.

Many of the studies dealing with the efficacy of antidepressants have expressed clinical improvement in terms of global scores and scales. These measures often rate changes in the depressive symptom complex *en masse* without taking into account whether a particular symptom is more or less responsive to a particular drug. While these global measures may accurately reflect overall changes in the patient's condition, on an individual basis, a patient may feel better in most respects yet may be bothered by a particular symptom that persists, or may be so pained by a symptom that its resolution is more urgent than treatment of the remainder of the depressive syndrome, which will improve in the deliberate way that often characterises antidepressant response. Although there have been studies examining the ability of certain symptoms to predict antidepressant response, there may be a difference between those symptoms that are useful in predicting response and those that are actually improved during treatment (Overall, 1975). Nelson *et al* (1984) correlated the improvement of items on the Hamilton Rating Scale for Depression with plasma levels of desipramine in an attempt to select symptoms that were prime indicators of the antidepressant effect. Improvement in symptoms such as depressed mood, hopelessness, guilt feelings, middle/late insomnia, loss of energy, somatic anxiety, and loss of appetite were felt to best indicate that the drug was working. However, this study did not have a placebo control, and other items that were not correlated with desipramine levels also improved over time. Other studies (Raskin *et al*, 1970; Montgomery & Asberg, 1979; Bech *et al*, 1981) have also arrived at lists of symptoms that are contended to resolve in close parallel with the action of the antidepressant. Common among the lists are depressed mood, anxiety, guilt feelings, decreased interest, and loss of energy.

In addition to the search for particular symptoms that are especially responsive to antidepressants, there have been efforts to see whether certain symptoms are more responsive to either of the two major groups of antidepressants, tricyclics and monoamine oxidase (MAO) inhibitors. Some reports have stated that tricyclics are the better treatment for endogenous symptoms (anhedonia, loss of appetite, late insomnia, a.m. diurnal variation, retardation), while MAO inhibitors are the treatment of choice for anxiety and other 'atypical' or non-endogenous symptoms (initial insomnia, increased appetite, p.m. diurnal variation, mood reactivity) (Ravaris *et al*, 1980; Nies, 1984). Others have found no difference between those symptoms that improved by tricyclics and those that improved by MAO inhibitors (Kay *et al*, 1973; Paykel *et al*, 1982).

A third issue that has not been well studied is the chronology of symptom resolution. The clinical improvement with antidepressants is often not an all-or-nothing phenomenon; symptoms often resolve at different rates. Perhaps there is a predictable sequence of symptom resolution with antidepressants in general, or with a particular class of antidepressant. This would be helpful in optimising the selection of an antidepressant for a particular patient.

Previously (Georgotas *et al*, 1986), we reported on the comparative efficacy of nortriptyline, phenelzine and placebo in depressed elderly in terms of global scores and scales. We found that both nortriptyline and phenelzine were significantly better than placebo, but not significantly different from each other. The outcome measures used were the total score on the Hamilton Rating Scale, the total score on the Zung

Self-Rating Scale, and Clinical Global Impressions Scale. The present report uses individual items of the Hamilton scale to examine which symptoms of depression are best treated with antidepressants as compared with placebo, whether some symptoms are better treated with either nortriptyline or phenelzine, and what is the order of symptom improvement.

Method

The study was conducted at the Depression Studies Program of New York University, an outpatient research facility for the study and treatment of affective disorders. Men and women, 55 years of age and above, complaining of depressive symptoms were evaluated for entry into this study. During the initial screening, the treatment plan and study requirements were fully explained, and written informed consent was secured. Patients included in the study were independently diagnosed by two psychiatrists as suffering from a major depressive disorder as defined by the Research Diagnostic Criteria (RDC) (Spitzer *et al*, 1977). A score of 16 or greater on the 21-item Hamilton Rating Scale for Depression (Hamilton, 1967) was also required for inclusion. Patients were excluded if they showed evidence of moderate to severe dementia, drug or alcohol dependence, a serious neurological disorder, or other pre-existing major psychiatric disorders. None of the patients accepted had psychotic features.

The patients were subsequently given a complete physical examination, ECG, and clinical laboratory evaluations to rule out active medical problems. Patients with chronic illnesses under control were included provided that they met the other criteria and had obtained clearance from their personal physicians. All patients accepted for the study were placed on dietary restrictions for MAO inhibitors.

Patients who met the entry criteria were administered placebo during a single-blind washout period of at least seven days. All antidepressants had been discontinued for at least one week prior to the placebo washout period. None of the patients had been treated with neuroleptics, lithium, carbamazepine, or MAO inhibitors during the year prior to this study. Any patient not meeting the entry criteria at the end of the washout period was not admitted to the double-blind portion of the study, which lasted seven weeks. Patients who were admitted were randomly assigned to one of three treatment conditions: nortriptyline (NT), phenelzine (PE), or placebo (PL). All three substances were in identical capsules which contained either 25 mg of NT, 15 mg of PE, or an inert substance. The initial dose of one capsule for three days was increased to two capsules on days 4–7. At the end of the first treatment week, the daily dose was increased to three capsules. Blood samples obtained at the end of week 2 were assayed for either NT plasma level or MAO platelet inhibition. Patients on NT who attained a plasma level in the range 50–160 ng/ml remained on three capsules. In patients whose levels were below this therapeutic window, the dosage was raised to four capsules, and if, on the basis of the sample taken at the end of treatment week 3, therapeutic levels had still not been achieved, the dose was raised to five capsules. A similar regimen was followed for patients on PE: those who did not attain a 70% or greater MAO inhibition by week 2 were prescribed a dose of four capsules, and the dose was raised to five capsules if the specified percentage MAO inhibition had not been achieved by week 3. The dose of placebo was also adjusted. In the event of side effects which interfered with functioning to a significant degree, dosage was decreased, irrespective of percentage platelet MAO inhibition or NT level. The doses were adjusted by the non-blind psychiatrist.

Patients completing fewer than 28 days of treatment for any reason were excluded from the final data analysis, except when significant drug-related adverse reactions required withdrawal of medication, or when there was a significant deterioration of clinical condition in any patient treated for at least 14 days. These patients were not included in the analysis because we felt that their treatment had not been given an adequate trial for determination of its efficacy or safety. All patients completing at least 28 days of active drug treatment were included in the final data analysis, except for those who failed to achieve NT levels within therapeutic range (50–160 ng/ml) or platelet MAO inhibition greater than 70% for at least two weeks, and those who were removed from the study due to other reasons not related to psychiatric pathology or study drugs, such as intercurrent illness, evidence of noncompliance, or alcohol or drug abuse. The therapeutic range for NT of 50–160 ng/ml was chosen based on the work of Sørensen *et al* (1978), and on our own previous study (Georgotas *et al*, 1983), which found that this range is applicable to the elderly. Previous studies (Robinson *et al*, 1978; Georgotas *et al*, 1981) have found optimal response with MAO inhibition ≥80%, and this was our aim in this study; however, in our recent experience with elderly patients, some cannot tolerate doses necessary for ≥80% inhibition and yet have a satisfactory response to PE with platelet MAO inhibition 70–80%.

At the end of the placebo washout period and during each weekly visit of the seven-week treatment period, patients were rated on the Hamilton Rating Scale by a psychiatrist blind to the patient's treatment condition. The symptoms to be studied were extracted from items on the Hamilton scale. The score of each item was taken as a quantitative measure of the severity of a symptom. In some cases, a symptom was represented by a combination of two Hamilton items. The 13 symptoms studied and their corresponding item(s) on the Hamilton scale were the following: depressed mood, 1; guilt feelings, 2; suicidal ideation, 3; initial insomnia, 4; middle/late insomnia, 5+6; retardation, 8; agitation, 9; psychic/somatic anxiety 10+11; appetite disturbance, 12; loss of energy, 13; weight loss, 16; and diurnal variation of mood – both a.m. and p.m., 18. The differences in effect of the three treatment groups on these symptoms were investigated using a multiple regression analysis with a repeated measures design as described by Pedhazur (1982). In this method, the criterion variable (depressive symptom) was regressed on the predictor variable (treatment) for all weeks of treatment. The pretreatment Baseline score for each criterion variable was partialled out of the analysis. A vector representing subjects by the means of their criterion variable over the treatment period was then entered into the regression equation. Consequently, the degrees of freedom associated with the subjects' vector and with the residual sum of squares were adjusted in determining the *F* ratio for testing statistical significance. Week-by-week comparisons of the Hamilton items used an analysis of covariance (ANCOVA) with the pretreatment Baseline score as the covariate.

Results

Patient sample

The double-blind treatment phase was completed by 90 patients, but only 75 were included in the data analysis. The reasons for excluding 15 patients from the data analysis were as follows: three (1 NT, 2 PE) did not comply with the protocol, two (1 PL, 1 PE) were terminated after a few days because of failure to obtain medical clearance for pre-existing cardiac problems, one (PE) was hospitalised within the first week because of clinical deterioration, five (1 PL, 2 NT, 2 PE) withdrew for reasons unrelated to treatment after two weeks or less and without having reached adequate NT levels or percentage platelet MAO inhibition, one (PE) was excluded for not having reached adequate percentage platelet MAO inhibition after seven weeks, one (PE) terminated after one week because of clinical improvement, and two (PE) self-terminated after one and three weeks because of failure to improve.

Of the 75 patients who met inclusion criteria for data analysis, 56 finished seven weeks of treatment. Reasons for the premature termination of 19 patients were as follows: 12 (11 PL, 1 NT) terminated because of clinical deterioration, three (1 PL, 2 PE) terminated because of clinical improvement, and four (2 NT, 2 PE) terminated early due to side effects.

Patients in the NT group had mean NT levels after week 2 in the range 82.6–95.3 ng/ml; the mean values of platelet MAO inhibition for phenelzine-treated patients were 68.3–81.1% after week 2, and exceeded 80% after week 5.

Patients were discouraged from taking other psychotropic medication during the study; however, 18 patients (24%) took small doses of sedatives/hypnotics for brief periods: seven PL patients (1 chloral hydrate, 3 flurazepam HCl, 2 temazepam, 1 chlordiazepoxide HCl), six NT patients (1 chloral hydrate, 2 lorazepam, 2 temazepam, 1 flurazepam HCl), and five PE patients (2 flurazepam HCl, 3 temazepam).

Overall treatment effect

Repeated measures analyses were performed comparing changes in the scores of selected items from the 21-item Hamilton Rating Scale over the seven-week treatment period among the three treatment groups; the pretreatment Baseline score for each item was partialled out of the analyses. The items investigated were the following: depressed mood, guilt feelings, suicidal ideation, initial insomnia, middle/late insomnia, retardation, agitation, psychic/somatic anxiety, appetite disturbance, loss of energy, weight loss, and diurnal variation—both a.m. and p.m. Items from the Hamilton scale representing depressed mood, guilt feelings, suicidal ideation, middle/late insomnia, agitation, anxiety, loss of energy, and a.m. diurnal variation had significant ($P < 0.05$) overall treatment effect, signifying that there were significant differences among the nortriptyline, phenelzine, and placebo groups in the outcome of these symptoms. No significant treatment effect was found for initial insomnia, retardation, weight loss, or p.m. diurnal variation, indicating that changes in these symptoms during the seven weeks were not significantly different among the three treatment groups. Pairwise comparisons of those items with significant overall effects were performed using a similar repeated measures model. Both nortriptyline and phenelzine were found to be significantly superior ($P < 0.05$) to placebo in reducing the scores on the Hamilton items for depressed mood, guilt feelings, suicidal ideation, agitation, anxiety, loss of energy, and a.m. diurnal variation of mood. No significant treatment effect on these items was found in comparing nortriptyline-treated patients with phenelzine-treated patients. However, nortriptyline was significantly better ($P < 0.05$) than either phenelzine or placebo in alleviating middle/late insomnia over the seven-week treatment period.

In summary, nortriptyline and phenelzine were significantly more effective than placebo in treating depressed mood, guilt feelings, suicidal ideation, agitation, anxiety, loss of energy, and a.m. diurnal variation of mood. Nortriptyline was significantly better than either phenelzine or placebo in treating middle/late insomnia. No significant differences were found in the effects that nortriptyline, phenelzine, and placebo had on the symptoms of retardation, appetite disturbance, weight loss, and p.m. diurnal variation of mood.

Chronology of symptom resolution

For those items on the Hamilton scale that had a significant overall treatment effect (depressed mood, guilt feelings, suicidal ideation, middle/late insomnia, agitation, psychic/somatic anxiety, loss of energy, and a.m. diurnal variation), weekly ANCOVAs, partialling out the Baseline score, were performed. The purpose of this was to compare the effects of the three treatments on a particular symptom on a week-by-week basis during the seven weeks of treatment. A statistically significant overall treatment effect ($P < 0.05$) at a particular week was followed by pairwise ANCOVAs. One of the first symptoms to show significant improvement was suicidal ideation. Nortriptyline patients had significant improvement in suicidal ideation as compared with placebo patients at week 2 ($P = 0.002$), and phenelzine patients had significant improvement in this symptom as compared with placebo patients at week 3 ($P = 0.014$). The next symptoms to be resolved were guilt feelings, psychic/somatic anxiety, and loss of energy. At week 4, patients treated with either nortriptyline or phenelzine had significant improvement ($P \leq 0.01$) in these symptoms as compared with patients treated with placebo. Not until week 5 was depressed mood significantly better ($P \leq 0.01$) in antidepressant-treated patients as compared with placebo patients. Nortriptyline-treated patients showed significant improvement ($P < 0.01$ in middle/late insomnia beginning at week 5; at no time were phenelzine-treated patients significantly better than placebo with regard to this symptom. The treatment effect on a.m. diurnal variation did not become significant until week 7, when those patients treated with either nortriptyline or phenelzine had significant resolution ($P<0.05$) of this symptom over patients treated with placebo. The above results are summarised in Table I.

In summary, with the exception of suicidal ideation, which had significant improvement beginning at week 2, the symptoms began showing significant treatment changes at week 4. For most of the Hamilton items, nortriptyline and phenelzine were significantly more effective than placebo, and both drugs became effective at the same time. The exceptions were suicidal ideation, for which the improvement over placebo became evident one week earlier in the nortriptyline group than in the phenelzine group, and middle/late insomnia, which responded significantly better with nortriptyline than with either phenelzine or placebo.

TABLE I
Chronology of improvement of depressive symptoms

Symptoms	*Week at which improvement became significant**
Suicidal ideation	2 (NT>PL), 3 (PE>PL)
Guilt feelings	4 (NT and PE>PL)
Anxiety	4 (NT and PE>PL)
Loss of energy	4 (NT and PE>PL)
Depressed mood	5 (NT and PE>PL)
Middle/late insomnia	5 (NT>PL), 7 (NT>PE)
Agitation	6 (NT and PE>PL)
Diurnal variation, a.m.	7 (NT and PE>PL)

*$P<0.05$ by ANCOVA with Baseline value as covariate.

Discussion

In the above study, the effects of nortriptyline, phenelzine and placebo on 13 symptoms of depression were investigated. The symptoms of depressed mood, guilt feelings, suicidal ideation, middle/late insomnia, agitation, anxiety, loss of energy, and a.m. diurnal variation showed significant improvement in patients treated with antidepressants as compared with patients treated with placebo. No significant difference in treatment response was found in the symptoms of initial insomnia, retardation, weight loss, and p.m. diurnal variation. That the former nine symptoms responded better to antidepressants than to placebo is not surprising and, in fact, is an elaboration on our earlier findings (Georgotas *et al*, 1986). The lack of a difference in response for the other four symptoms may reflect several things. First, although many of our patients complained of weight loss prior to entering our study, very few of our patients actually lost weight during the seven weeks of treatment, even if they were not clinical responders. This may explain the failure to find a significant treatment difference in weight loss. Although patients were generally forbidden to use other psychiatric drugs during the study, in some cases of severe insomnia, patients were given mild hypnotics for short-term use; in addition, some patients had long-standing complaints of initial insomnia that antedated the onset of illness and, in fact, some patients who responded still complained of difficulty falling asleep. These may explain the lack of a statistically significant difference in the response of initial insomnia to the three treatments. The failure of retardation and p.m. diurnal variation to respond differently may be due either to methodological limitations or to the lack of an actual drug/placebo difference.

When the responses to nortriptyline and to phenelzine were compared, eight of the nine symptoms studied were treated with equal efficacy by either drug. The effect of nortriptyline on symptoms appeared to be similar to that of phenelzine, regardless of whether the symptoms were endogenous or non-endogenous. The exception was middle/late insomnia, which was significantly improved by nortryptyline as compared with phenelzine. Except for the latter symptoms, these results corroborate other studies (Kay *et al*, 1973; Paykel *et al*, 1982) that found no difference in symptom response between tricyclics and MAO inhibitors. Even the purported selective anti-anxiety effect of MAO inhibitors (Ravaris *et al*, 1980) was not supported by this study. Other things being equal, nortriptyline and phenelzine appear to be equally effective in the general treatment of major depression, with nortriptyline better than phenelzine in improving middle/late insomnia.

Most of the symptoms of depression did not show significant improvement until the fourth week of treatment. The exception was suicidal ideation, which improved by the second week in nortriptyline patients and in the third week in phenelzine patients. Otherwise, the order of symptom resolution was similar for both drugs. There did not appear to be differences in the time of resolution between, say, psychic versus somatic symptoms, or endogenous versus non-endogenous symptoms. It should be emphasised, however, that although differences between drug and placebo patients began to appear at week 2, some symptoms such as agitation and a.m. diurnal variation were not significantly improved until the sixth or seventh week of treatment. Thus, in addition to the lag period before the onset of antidepressant action, the actual time to complete recovery from the onset of action may be as long as a month.

The above findings emphasise again that both nortriptyline and phenelzine are effective in treating major depression in depressed patients over the age of 55. Except for nortriptyline's superior effect on middle/late insomnia, neither drug appears to be especially selective in relieving certain symptoms of depression. In addition, the resolution of the symptom complex may be stretched over a period of four or five weeks. Given the usefulness these results have in adjusting our expectations of the effects of antidepressants, further research is needed to refine this information into clinically useful guidelines.

Anorgasmia from Clomipramine in Obsessive-Compulsive Disorder

A Controlled Trial

W. O. MONTEIRO, H. F. NOSHIRVANI, I. M. MARKS and P. T. LELLIOTT

Forty-six patients with obsessive-compulsive disorder undergoing a double-blind controlled study of clomipramine and placebo were interviewed to assess changes in sexual function. Of 33 patients with previously normal orgasm, nearly all of the 24 on clomipramine developed total or partial anorgasmia; none of the 9 on placebo did so. Anorgasmia persisted with minimal tolerance over the five months that clomipramine was taken. Men and women were equally affected. Sexual side-effects are easily missed without a structured interview, and can detract from the value of drug treatment.

It has been known for many years that psychotropic drugs can disrupt sexual function (Singh, 1961; Shader, 1964; Blair & Simpson, 1966). Many case reports have implicated tricyclic antidepressants (TCAs), and in particular clomipramine, as a cause of low libido, delayed or absent orgasm, and absent or retrograde ejaculation (dry orgasm) (Beaumont, 1973, 1977; Couper-Smartt & Rodham, 1973; Nininger, 1978; Thoren *et al*, 1980; Yassa, 1982; Quirk & Einarson, 1982; Sovner, 1983). Premature ejaculation is sometimes treated with TCAs (Eaton, 1973; Correa & Traldi, 1977; Abraham & Porto, 1978), although a controlled investigation of clomipramine did not show a useful effect (Goodman, 1980).

The pathophysiology of these effects is not well understood. Various sites of action have been implicated, both central (serotonergic or prolactinaemic) and peripheral (anticholinergic, or alpha-adrenergic blocking) (Beaumont, 1973; Everitt, 1977; Barnes *et al*, 1979; Kulik & Wilbur, 1982; Sovner, 1983; Shen, 1983).

Little is known about the incidence of sexual side-effects of drugs. In an uncontrolled study of 51 depressed patients, 65% of whom had prior sexual dysfunction, a low dose of clomipramine adversely affected sexual function in 20% and improved it in 50% (Beaumont, 1977). Manufacturers' reports and pharmacological textbooks suggest that sexual side-effects from antidepressants are minor. Controlled studies of clomipramine for obsessive-compulsive disorder (OCD) confirm this impression (Marks *et al*, 1980; Ananth, 1980; Insel *et al*, 1983), although Thoren *et al* (1980) do mention anorgasmia as a side-effect.

During a replication of a double blind controlled study comparing a 35 week course of clomipramine with placebo in OCD, some patients complained about sexual side-effects. This led us to examine all the patients in a structured interview.

Method

Sample

Forty-six patients with severe OCD (ICD-9 (World Health Organization, 1978) and DSM-III (American Psychiatric Association, 1980) criteria) were randomly assigned to clomipramine or to placebo in a 3:1 ratio in a controlled double-blind study of clomipramine and exposure treatment. Of these, 33 (24 on clomipramine, 9 on placebo) had enough prior regular sexual activity with orgasm to enable assessment of the subsequent sexual side-effects of medication; of the 33, 21 (16 on clomipramine, 5 on placebo) had no previous sexual dysfunction.

Procedure

Patients were informed that they would have either drug or placebo, but were not warned of any sexual side-effects. The drug was provided in 25 mg capsules, starting with one per night and increasing by one capsule every three nights to eight capsules per night. Complaints about side-effects were met with reassurance, and any attribution to the drug noted without comment.

Assessments

Patients and assessor were initially blind as to drug condition. A psychiatric interview and a urine screen for psychotropic drugs were administered at the start of the study (week 0). The self-rated Beck Depression Inventory (Beck *et al*, 1974) (13 items, score range 0–39) and the assessor-rated Hamilton Rating Scale for Depression (Hamilton, 1969) (17 items, score range 0–52) were administered in weeks 0 and 8, as was the self-rated Physical Symptom Questionnaire (Marks *et al*, 1980) (12 items, score range 0–36). Drug dose and plasma levels were checked in weeks 4 & 8. The following assessments were made of sexual function: (a) spontaneous complaints of sexual dysfunction; (b) changes in sexual relationships; (c) effect of being tense or being sedated on sexual function; (d) effect of OCD on sexual function; and (e) attribution of sexual dysfunction and of side-effects; these data were recorded whenever complaints arose, and also at week 8.

A structured interview enquired into changes in sexual interest and urge, ability to fantasise, spontaneous sexual fantasy, changes in erection or lubrication, frequency of sex, sexual sensation, length of time to orgasm, and the intensity, enjoyability, occurrence of and ease of orgasm at intercourse and at masturbation, pain at orgasm or when emptying the bladder, and occurrence of dry orgasm. Most patients did not know whether they had sexual dreams, and information on these was left out of the results.

Results

The mean age of the 46 patients was 31 (s.d. 9.4 years). There were 25 men (13 single, 11 married, 1 divorced) and 21 women (9 single, 11 married, 1 divorced).

Sexual function before treatment

This information was obtained at routine assessment, so the dysfunction recorded may be an underestimate. Twenty-one patients (9 men, 12 women) had apparently unproblematic heterosexual sex lives; 16 were put on clomipramine and 5 on placebo.

Sexual problems in the remaining 25 patients (mean age 30, s.d. 9.6 years) are summarised in Table I. For inclusion the shyness, reduced libido, phobia about sex, or guilt had to be sufficient to grossly interfere with their ability to form sexual relationships or have coitus. Sexual deviation is also recorded. The mean age of the 11 virgins was 26 (s.d. 6.9 years). One patient who had not had sex for many years had a wife who had vaginismus and was still a virgin; they refused treatment for this problem. Another patient with low libido and his wife were only able to have sex when drunk. Of these 25, 12 had enough sexual activity to orgasm to be included; eight were put on clomipramine and four on placebo.

Change in sexual function

Marital relationships remained stable. Change in sexual function could not be assessed in 13 of the 46 patients; of these 13, information from one was unreliable, another only had sex after drinking, one had anorgasmia, two had missing data and eight had no sexual activity during the 35 weeks of the trial. The following results come from the remaining 33 patients (mean age 32) who had enough sexual activity to orgasm to allow us to assess the effect of clomipramine. They include the 21 patients with unproblematic sex lives.

Placebo patients ($n = 9$; 4 men, 5 women). Three developed slight sleepiness that interfered minimally with sexual function, and one increased in sexual interest. There were no spontaneous or elicited complaints of change in sexual function or orgasm. They were on a mean of 175 mg (range 100–200 mg) of placebo.

Clomipramine patients ($n = 24$; 17 men, 7 women). The results are summarised in Table II. There were no com-

* = No orgasm at all

plaints of sexual dysfunction from sedation or inability to fantasise sexually. Spontaneous sexual thoughts did not change. Eight of the nine patients (7 men, 2 women) reporting decreased interest in sex attributed it to difficulty in achieving orgasm; five of the eight were among the eight who spontaneously complained about drug-induced sexual dysfunction. Seven (4 men, 3 women) patients said they were having less coitus or masturbating less often – five attributed it to difficulty in reaching orgasm. Only 2 of the 17 men reported problems with erection and 2 of the 7 women with lubrication; these effects were slight. Seven patients (4 men, 3 women) reported reduced sexual sensation, two attributing it to disinterest due to anorgasmia.

Of the 24 patients on clomipramine, 22 reported much greater effort, took longer and were often unable to achieve orgasm; 18 of these 22 (13 men, 5 women) were unable to attain orgasm at all even after prolonged effort, although all 24 had been orgasmic previously. One woman could occasionally achieve orgasm with masturbation, but not with coitus, during which she had always been orgasmic previously. The other four (3 men, 1 woman) were intermittently anorgasmic while on the drug. Most (number not recorded) of the 14 in whom clomipramine reduced intensity and enjoyability of orgasm attributed it to the effort involved in reaching it. Four men reported pain at orgasm, and 3 men had pain on micturition which lasted two or three weeks and disappeared although they continued clomipramine. No man reported orgasm without ejaculation (dry orgasm).

The mean dose of clomipramine at the time of interview was 140 mg (range 25–200 mg). Most patients noticed marked difficulty in achieving orgasm within the first few days and often at the first sexual activity after starting the capsules, when on a dose no higher than 25–50 mg. Total anorgasmia was usual after 100–150 mg. Most found it hard work trying to reach orgasm and became frustrated and disinterested in sex. Some wondered if they had developed a permanent sexual problem, and were relieved to discuss this. Only two patients developed any tolerance at all; after 2–3 months they became able with great difficulty to attain orgasm occasionally while remaining on clomipramine. Five patients insisted on reducing and occasionally stopping their drug due to anorgasmia.

Return to normal sexual function occurred within three days of stopping clomipramine in all except one man. Although he had been symptom-free before starting clomipramine he developed slight impotence and loss of libido after drug withdrawal, which improved three months later without treatment. Of the 24 patients on clomipramine only 2 found orgasm unchanged: one refused to take more than 25 mg, as she experienced vague but intolerable side-effects, and the other was a transvestite who had been masturbating

20 times a week; he was asked to reduce this to twice a week and became able to attain orgasm again, despite a dose of 150 mg of clomipramine.

Physical Symptom Questionnaire

Neither the 9 placebo nor the 24 clomipramine patients rated themselves as being significantly different at week 8 compared with week 0, either on the total scores or on the item enquiring about sexual difficulties. Of the ten who reported no side-effects on this self-rated questionnaire, three nevertheless spontaneously complained of anorgasmia, and eight of them reported complete anorgasmia at interview.

Depression ratings

There were no significant differences (*t*-tests), at week 0 or at week 8, between the clomipramine and placebo groups on either the Beck or Hamilton questionnaires.

Laboratory tests

Urine screen at week 0 confirmed that all patients were free of any psychotropic drug. Plasma levels at week 4 and week 8 confirmed that no placebo patient was on clomipramine. In patients on clomipramine, plasma levels of drug and metabolite reached therapeutic levels: clomipramine 97 ng (s.d. 48 ng) at week 4 and 89 ng (s.d. 79 ng) at week 8; and desmethylclomipramine 190 ng (s.d. 102 ng) at week 4 and 225 ng (s.d. 105 ng) at week 8). Nearly every instance of severe anorgasmia began within the first week when plasma levels must have been very low.

Discussion

Sexual function before treatment

We were surprised at the amount of sexual pathology in our obsessive-compulsive patients; 24% of our sample were virgins at a mean age of 26 and another 9% had not had sex for years. We do not know how this proportion compares with that in other anxiety disorders or in normals.

Sexual side-effects of clomipramine

Patients were free of other drugs. Sexual function in the nine placebo patients remained unchanged. Within days of starting clomipramine 92% of the patients (96% of those on more than 25 mg per day) developed great difficulty in achieving orgasm, most to the point of being anorgasmic; 70% became totally anorgasmic by the time their dose of clomipramine had reached a therapeutic level. Men and women were equally affected.

The sexual problem from clomipramine solely concerned orgasmic and ejaculatory capacity, not other aspects of sexual function. Clomipramine did not reduce frequency of spontaneous sexual thoughts, ability to fantasise, or interest in sexual intercourse; patients were able to achieve erection or lubrication normally. Clomipramine-induced anorgasmia led to patients feeling frustrated, and many found sex less enjoyable. A few patients on clomipramine developed pain at orgasm or on micturition. Depression scores in both groups were comparably low before and during treatment, so the anorgasmia after starting clomipramine could not have been due to depressed mood. Sedation was minor and did not affect sexual function.

Tolerance hardly ever developed. The main interview was carried out at week 8, although most patients had also been assessed earlier. In the 6 months that patients were on the drug only 2 of 22 became at all tolerant to it, and even they found that orgasm was more difficult to achieve than when off the drug.

Delay in achieving orgasm began early, possibly by the time of the first sexual activity after starting clomipramine. Return to normal was equally fast, occurring within 1–3 days of stopping the drug. Other reports confirm this (Nininger, 1978; Quirk & Einarson, 1982; Schwarcz, 1982; Shen, 1982). Although it is common knowledge that antidepressants can retard ejaculation it is not generally realised quite how much clomipramine impairs orgasm in both sexes. The extent of this handicap is emphasised by our present findings and substantially diminishes the therapeutic value of clomipramine. It is not surprising that five of our patients reduced and occasionally stopped the drug because of its sexual side-effects. Similar problems might be found on closer study of other antidepressants. If such were found, this would diminish the utility of these drugs.

McLean *et al* (1983) reported orgasm on yawning in two patients on clomipramine. Our sample made no such report during an intensive interview on sexual behaviour, although we did not enquire directly about it.

Assessment of sexual dysfunction in drug trials

Given that 96% of our sample who were all previously orgasmic developed anorgasmia on clomipramine, there have been surprisingly few reports of this side-effect in the many controlled trials of the treatment of obsessive-compulsive, phobic and depressive disorders (reviewed in Marks, 1983). Numerous case reports implicate TCAs and monoamine oxidase inhibitors (Friedman *et al*, 1978; Rapp, 1979; Lesko *et al*, 1982; Christenson, 1983; Pohl, 1983) in sexual dysfunction.

Sexual side-effects are probably common and under-reported in drug trials because they are so easily missed. Most patients report sexual side-effects only when directly and specifically questioned about them, and not on simple questionnaires. The physical symptoms questionnaire that we used to elicit side-effects did not ask directly about orgasm, only that patients should rate 'sexual difficulties' on a 4-point scale from 'no problem' to 'severe'. Clomipramine and placebo patients gave similar answers to this question; 36% of those with drug-induced anorgasmia at intervew did not admit to any sexual difficulty on the questionnaire in spite of their concern about it and even though some were secretly reducing their dose of clomipramine in an attempt to regain their lost orgasmic capacity. In a previous controlled trial (Marks *et al*, 1980) this questionnaire also failed to detect any difference in sexual side-effects between clomipramine and placebo patients. It is evident that more direct and specific questioning is needed to detect these. About a third of patients on clomipramine spontaneously complained of sexual problems, and this prompted us to interview all the patients in more detail.

The failure of patients to report anorgasmia is remarkable. The same failure of reporting is found with thioridazine; 50% of patients in the study of Kotin *et al* (1976) had problems with ejaculation and 33% had dry orgasms, yet in the 17 years that thioridazine had been used prior to that study (12–15 million patients) only 31 cases of ejaculatory failure were reported to the manufacturers and there were only ten published articles reporting 18 cases.

The blindness of assessors to drug condition has been questioned, as the dry mouth of patients on TCAs is immediately evident to the experienced observer (Couper-Smartt & Rodham, 1973; Leyburn, 1967). Nevertheless, in a previous trial examining clomipramine in OCD assessors remained blind to drug condition (Marks *et al*, 1980). However, once alerted to the range of side-effects, including anorgasmia, assessors in the present study were able to guess the patients' drug condition. The patient's blindness, too, must necessarily be questioned in trials of this kind. The problem of maintaining rater blindness will be discussed in more detail in our main report of this trial.

Mechanism of anorgasmia from clomipramine

Identification of the mechanism of anorgasmia from clomipramine might well illuminate the normal physiology of orgasm. Anorgasmia begins within three days (perhaps hours) of starting clomipramine, and returns to normal three days after stopping it. The antidepressant effect takes 12–14 days, as does the uptake of clomipramine into fat; the anorgasmia therefore cannot be due to these factors. Nor is it likely to result from the sedation that can occur 2–3 days after starting clomipramine, because complaints of sleepiness were minimal and patients said this did not affect sexual function. Delayed orgasm is unlikely to be mediated by the central serotonin or noradrenaline reuptake blocking effect of clomipramine (Barnes *et al*, 1979). Although clomipramine has prominent anticholinergic effects, other anticholinergic drugs such as atropine do not necessarily cause anorgasmia even in doses large enough to cause pupil dilatation, tachycardia and extremely dry mouth (Wagner & Brindley, 1980). Moreover, similar anorgasmia is reported with monoamine oxidase inhibitors (Friedman *et al*, 1978; Rapp, 1979; Lesko *et al*, 1982; Christenson, 1983; Pohl, 1983).

Beaumont's (1973) suggestion that alpha-adrenergic blockade causes anorgasmia is probably wrong. Both phenoxybenzamine (Wagner & Brindley, 1980) and phentolamine (Brindley, personal communication) cause failure of external ejaculation (dry orgasm) but have no significant effect on the ease with which orgasm can be produced. Occasional case reports suggest that desipramine (which is largely noradrenergic) may not block orgasm in the way that many other TCAs do (Quirk & Einarson, 1982; Sovner, 1983); it does not have much anticholinergic, alpha-adrenergic blocking or serotonergic activity. We do not know how other TCAs affect sexual function. Clomipramine-induced anorgasmia does not result from reduced genital sensation, which patients who had delayed or absent orgasm reported to be negligible.

Evaluation of the literature of sexual dysfunction due to drugs would be easier if reports specified which aspect was disrupted, e.g. libido, orgasm or ejaculation, and whether a control group was included in the study.

In conclusion, a structured interview revealed that anorgasmia became the norm, not the exception, in obsessive-compulsive men and women on clomipramine.

Outcome in Bipolar Affective Disorder After Stereotactic Tractotomy

Nine patients have been treated by subcaudate stereotactic tractotomy for bipolar affective disorder resistant to drug treatments. In the majority, after the operation there was a reduction in frequency and severity of depressive and manic episodes. There was a trend for the operation to have more effect on the manic than on the depressive phases. Drugs which had been inert previously sometimes became therapeutically useful after surgery.

The history and development of psychosurgery has been reviewed by Bridges & Bartlett (1977). Current techniques bear little resemblance to earlier methods. Side-effects are now unusual, and changes in personality are rare. The main indication for subcaudate stereotactic tractotomy (SST) has been unipolar affective disorder, and there has been some doubt about the suitability of this operation for patients suffering from bipolar illness. The main concern was that if there were any tendency to disinhibition after the operation, this might result in a shift of the illness towards hypomania (Bartlett *et al*, 1981).

We present nine case studies of patients suffering from bipolar illness, who were referred from Whitchurch Hospital, Cardiff to the Brook Hospital, London, where they underwent SST. Six of these have been observed for at least seven years following the operation. The patients had long histories of well defined phasic manic and depressive disturbances in mood. All were severely incapacitated by the disorder and were failing to benefit from the treatments available at the time and, in particular, no longer responded to lithium. Some had reached the stage of rapid recurrences with no or minimal periods in remission. In each case the uncertainty about the outcome was explained to patients and relatives.

Case reports

The patterns of illness for each patient are summarised in Fig. 1.

Patient 1 (Female, born 1931) The patient's first episode of depression followed the birth of her second child; the second followed a partial thyroidectomy. After two years of good health she relapsed into a mixed affective state. Treatment was only partially effective, and the development of rapid cycling illness led to SST (eight seeds bilaterally) being performed. One year after the operation she went into a complete remission for six years. All this point she became hypomanic, and a year later was prescribed lithium for a further attack. A recent depressive episode has responded well to a tricyclic antidepressant. None of the postoperative episodes have been as severe as those before surgery.

Patient 2 (Female, born 1917) This patient had a puerperal depression preceeded by a history of minor mood lability. She then developed recurrent depressive episodes, with one mild episode of hypomania; her first definite manic episode occurred at the age of 57. Since treatments became increasingly ineffective, she underwent SST (seven seeds bilaterally). In the first two years after the operation she had five episodes of depression, and she was referred for an extension. This was prevented by her poor respiratory function. However, the time spent in illness over the next two years reduced, and her depression was attenuated and is now responsive to tricyclic antidepressants.

Patient 3 (Female, born 1907) This patient had her first depressive episode when aged 53; 14 years later, following her first episode of hypomania, she developed a rapid cycling mood disorder and at the time of SST (five seeds bilaterally) she was continuously ill. After the operation she had mild depressive episodes about once per year, which responded to mianserin. She was on lithium until the age of 75, when this was changed to carbamazepine on account of drug induced tremor. Since SST there has been a reduction in severity and frequency in depressive episodes; a hypomanic episode did not recur for six years.

Patient 4 (Female, born 1921) Following the death of her parents, this patient suffered from frequent episodes of mania and depression, and SST (eight seeds bilaterally) was performed when she was 56 years old. The lesion was extended four years later (four seeds bilaterally). Following the first operation, hypomanic phases became less severe but depressive episodes continued with unabated severity, and remained unresponsive to drugs. Following extension of the operation, she developed continuous partial epilepsy. The computerised tomography scan showed embolic damage in the right frontal region; this was attributed to earlier embolic episodes due to mitral valve disease. The epilepsy was controlled, but rapid cycling of mood continued, although the manic episodes were less severe. She had a left-sided stroke eighteen months after the second operation.

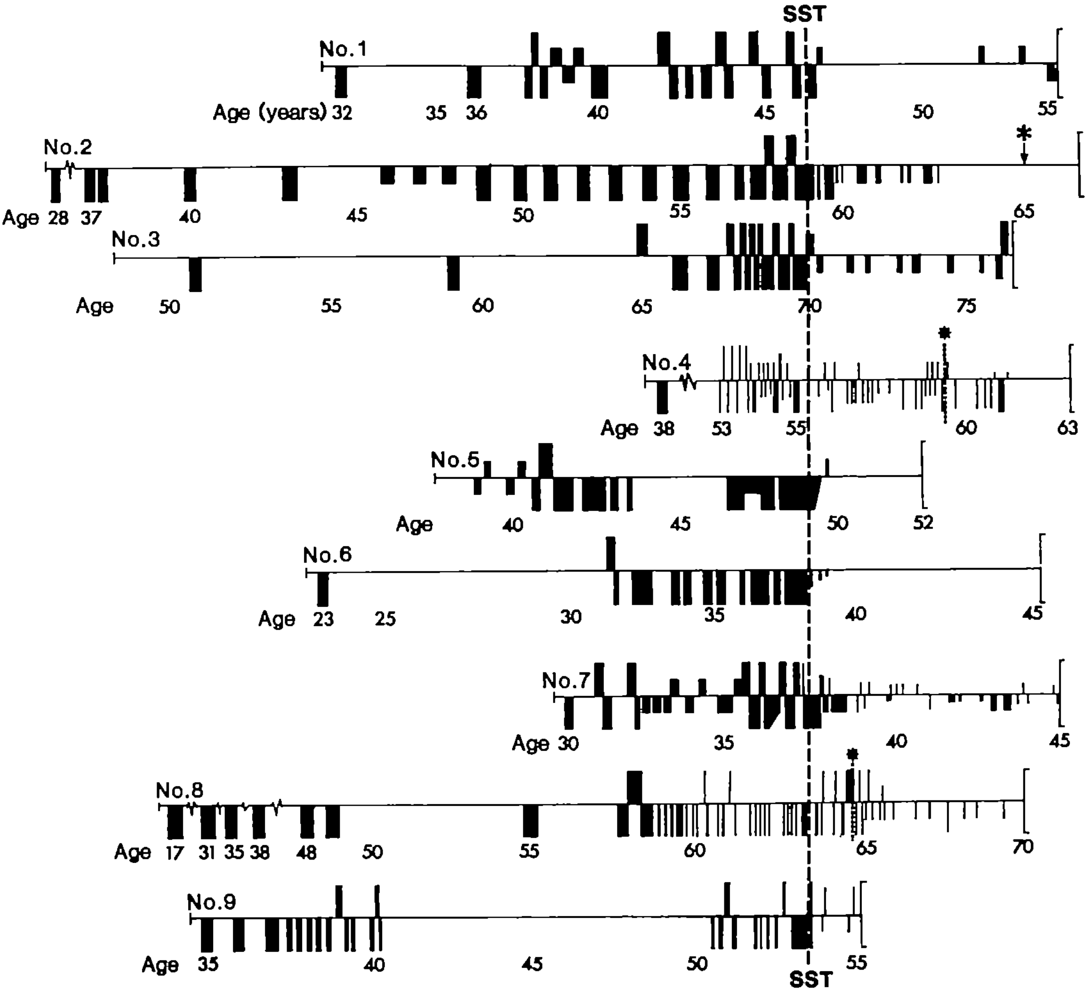

FIG. 1 Follow-up of nine patients. The time axis is in years, and represents the age of the patient. Entries above the axis represent manic episodes, and those below the axis depressive episodes; the degree of mania or depression is indicated by the height or depth of the marker. An asterisk shows the time of death; a star marks the time of extension of subcaudate tractotomy.

Patient 5 (Male, born 1933) This patient developed mood swings following a two-year history of anxiety symptoms. Because of his anxiety he was prescribed increasingly larger doses of chlorpromazine; attempts to withdraw this precipitated depressive episodes. Although the mood disorder was resistant to treatment, behaviour therapy partially controlled his phobic symptoms. Following two years of almost continuous depression, he underwent SST (ten seeds bilaterally). One year after surgery he was free from anxiety, phobic or affective symptoms. He has remained well to the time of follow-up.

Patient 6 (Female, born 1940) This patient's first depression followed the birth of her only child. Eight years later she developed a cyclical mood disorder which, despite treatment, progressed into almost continuous illness for the 18 months before SST (eight seeds bilaterally). Since the operation she has been free of major mood disorder, although after the death of her mother and the birth of a grandchild she developed a phantom pregnancy of nine months duration, which resolved spontaneously.

Patient 7 (Male, born 1940) This patient developed depression following the break-up of a homosexual relationship. He then had mood swings of increasing frequency, resistant to all treatment. Following SST (eight seeds bilaterally) manic phases were less severe, but depressive phases continued unabated. These have since responded to a combination of lithium, clomipramine and tryptophan. The substitution of carbamazepine for lithium has been beneficial. Stopping medication precipitated a further depressive episode.

Patient 8 (Female, born 1914) This patient's first depressive episode occurred after she failed her school certificate. Further depressive episodes occurred periodically until the age of 58 years, when she developed rapidly cycling affective disorder. Although treatment of acute episodes was partially successful they occurred with increasing frequency, and prophylaxis was impossible because of lithium intolerance. Continuation treatment with antidepressants was unhelpful. The SST (eight seeds bilaterally) had little effect, and an extension was performed a year later (left side four seeds, right side six seeds). She continued to have mood swings, but these now proved responsive to previously ineffective medication. In the past three years carbamazepine has increased mood stability.

Patient 9 (Female, born 1931) This patient developed agitated depression following a subarachnoid haemorrhage. After a time of rapid cycling she responded to a combination of a monoamine oxidase inhibitor, a tricyclic antidepressant and lithium, which was discontinued on admission to a general surgical ward. She then redeveloped resistant rapid cycling. The SST (ten seeds bilaterally) was performed when she was 54 years old, and follow-up is limited. Since the operation she has had five periods of illness, some of which were accompanied by persecutory delusions and auditory hallucinations. In the patient's opinion episodes of illness have been reduced in frequency and severity; in particular, the depression has been relieved more than the hypomania. However, before SST the patient never experienced first rank symptoms. The possibility of SST precipitating schizophrenic psychosis must be considered.

Discussion

Case studies of the type described here have a number of limitations. Data collection is retrospective and relies on case-notes. Those patients who have done best tend to have least contact with the psychiatric services, so that detailed information on them is unavailable. The following conclusions concerning outcome following SST are limited by the lack of a control group and the controversy which exists with regard to the course of affective disorder. Angst (1981) reports that this is one of decreasing cycle length and increasing number of episodes, whereas Bland (1985) suggests a more benign course where cycle duration remains constant. If this latter view is correct, then improvement following SST may be merely due to chance variations in vulnerability to illness or placebo effects.

The placebo response to such a dramatic therapy, however, may be less of a problem. It might be anticipated that placebo responses would be immediate and of relatively short duration, and this does not accord with the observed latent period before improvement appears. Those holding the view that affective illness of the kind described here does not deteriorate with time may ascribe this latent period to a result of the patient living through the latter part of a vulnerable phase. In general the patterns depicted in Fig. 1 do not support this conclusion.

With these reservations in mind, and bearing in mind the small sample size, the following tentative conclusions may be drawn.

(a) All patients have reported a reduction of frequency and severity of episodes of illness.
(b) Hypomanic episodes have been more sensitive to SST than depressive episodes, in that they have either stopped or occurred in a very attenuated form. In one case the converse may be true.
(c) In five patients, drugs which were ineffective before SST appeared to become effective subsequently; two patients continue to require no medication. Where carbamazepine has been used postoperatively, it may improve mental stability further.
(d) Instability of mood as seen before the operation may continue in the first year following SST.
(e) The recrudescence of mood cycling in the first patient following six years in remission, and the occurrence of a hypomanic episode in patient No. 3 after being well for six years, raises the question of whether this operation has a time-limited efficacy, due perhaps to ageing.
(f) The unsuccessful course of the fourth patient suggests that SST should not be used in patients with cerebral damage.
(g) Previous reports stated that SST is an effective treatment for anxiety (Göktepe *et al*, 1975; Strom-Olsen & Carlisle, 1971). A patient in whom anxiety and phobias were a prominent feature had early relief from these symptoms, but this was a single case and a complex situation.

Thus it would appear that, far from causing a shift towards hypomania, SST attenuates hypomanic episodes more effectively than depressive episodes, although many have experienced attenuation of both. The need to continue medication following operation points to the use of SST as an aid rather than a cure; this palliation may only be temporary, although for those patients who have had severe chronic illness it must be remembered that any respite is welcome. Where carbamazepine has been used, mental stability appears to have improved. The new generation of mood stabilising drugs such as carbamazepine and sodium valproate have not been in use until recently. It may be that these drugs will make SST unnecessary in the future.

Acknowledgements

We would like to acknowledge the careful, courteous and professional treatment given to these patients by Dr P. K. Bridges and Mr J. Bartlett and their team at the Brook Hospital, and to thank the patients for agreeing to be assessed for this study. Dr D. M. Shaw is a member of the external staff of the Medical Research Council.

Bipolar Affective Disorder in Down's Syndrome

Recent literature reports suggest that the presence of Down's syndrome precludes the development of mania. A case of bipolar affective illness in a man with Down's syndrome is presented.

The presence of bipolar affective disorder in mentally handicapped people is well documented (Corbett, 1979; Hasan & Mooney, 1979; Heaton-Ward, 1977; Reid, 1972; Russell, 1985; Sovner & Hurley, 1983). An extensive literature review by Sovner *et al* (1985) identified 28 cases of major depressive illness but no reported case of mania in Down's syndrome, and they propose the hypothesis "that Down's syndrome may preclude the development of mania". We present a case that casts doubt on this hypothesis.

Case report

Mr W is a 26 year-old severely mentally handicapped non-verbal ambulant man with Down's syndrome. He is a resident in a bungalow unit with nine other severely mentally handicapped people. He is transported daily to a long term training centre, and visits his elderly parents' home most weekends. There is no family history of affective illness. He was admitted to residential care in spring 1983 because of the inability of his ageing parents to cope with his intermittent aggressive and disruptive behaviour. He is mischievous by nature, and has a tendency to upturn chairs and small furnishings in an attention-seeking manner.

In early July 1984 he became withdrawn and quiet, and would sit passively, with loss of interest in his surroundings and loss of appetite. He appeared less happy, cried frequently and was increasingly aggressive towards staff. During a three week period of observation no precipitating environmental features or physical illness could be identified. He lost 4 lbs in weight. A diagnosis of depressive disorder was made, and he was started on amitriptyline (25 mg at 6 p.m. and 50 mg nocte). This dosage produced excess sedation, necessitating reduction in the first week and continued reduction until discontinuation three weeks after commencement. His mood had improved somewhat while on the medication, and he returned to a normal mood at the beginning of September 1984.

In late September he suddenly began to show sleep disturbance: he slept for approximately 2 hours per night for six consecutive nights. He became increasingly destructive with constant hyperactivity, his vocalisations increased significantly, and he became loud and boisterous. He was aggressive with staff and had regular protracted episodes of inappropriate laughter, particularly when alone. His predeliction for overturning small furnishings expanded to large beds and tables, and he needed constant supervision. Staff described him as "wound up".

Physical examination (including dental assessment), biochemical investigation, and thyroid function tests were all normal. During a 10-day observation period no change was made in his normal daily programme, and his symptoms continued in the training centre and in the setting of the residental home. At weekends his parents found him totally unmanageable and commented on his "amazing energy". Hospital admission was considered, but he was treated in a residential setting with haloperidol (5 mg t.d.s.), thioridazine (100 mg nocte) and individual nursing. He improved significantly in the next four weeks: he slept better with no violent or explosive episodes, but continued to be hyperactive and mischievous, with unpredictable episodes of laughter and shouting. He continued a fluctuating improving course; medication was gradually reduced and finally discontinued in February 1985. Since then he has continued well, and his mood is normal in a residential, training and home setting.

A month-long period of mild but similar symptomatology in 1978 was later recalled by the patient's father.

Discussion

The diagnosis of psychiatric illness in mentally handicapped people presents a considerable challenge to the clinician, particularly when confronted with severely mentally handicapped people who have no language skills. Accurate diagnosis can be made by careful monitoring of behavioural, social and physiological parameters (Reid, 1972) and by comparing the patient's normal behaviour with that which he or she exhibits during the period of instability (Rivinus & Harmatz, 1979).

It could be argued that this manic episode was induced by tricyclic antidepressant medication. This argument seems improbable, as the initial dosage was small and was reduced further before discontinuation. Total duration of tricyclic treatment was 3 weeks, and the patient was medication-free for 6 weeks prior to the onset of mania.

In view of the association between Down's syndrome and thyroid disease (McCulloch *et al*, 1983) thyrotoxicosis was considered, but was ruled out on physical examination and biochemical investigation.

The case presented meets ICD-9 (World Health Organization, 1978) criteria for the diagnosis of mania and demonstrates that bipolar affective illness and Down's syndrome can co-exist.

Monitoring the Occurrence and Duration of Electroconvulsive Fits

During 100 routine psychiatric hospital electroconvulsive treatments the medical staff administering treatment experienced little difficulty in deciding that a fit had occurred. The judgement was based on simple clinical observation of a succession of clonic bodily movements, and high inter-rater agreement was found for the measurement of fit duration. The cuff technique was also used, but it tended to underestimate fit duration and is not recommended for routine ECT practice.

Pippard & Ellam (1981) refer to medical staff incorrectly accepting the tonic contraction of body musculature at the time of application of the electrical stimulus as evidence that a fit has occurred. It has also been suggested that 'missed seizures' with unilateral electroconvulsive treatment (ECT) might account for the bias toward bilateral ECT. The problem is that muscle relaxants may abolish the muscular activity associated with a seizure, so what should doctors accept as adequate evidence of a therapeutic convulsion?

Christensen & Koldbaek (1982) recommended that ECT should be monitored by concurrent electroencephalogram (EEG). They claimed that 43% of 156 treatments appeared to be inadequate if judged by clinical observation alone, but EEG recording proved that only 9% had really failed. This work has been criticised by Brumback (1983), who pointed out several difficulties of interpretation if only bifrontal EEG electrodes were used. EEG monitoring of ECT, although perhaps the best reference standard, involves the use of delicate and expensive recording apparatus, and takes a considerable time. Autonomic changes provide evidence that a fit is occurring, but do not indicate its duration (Watkins-Pitchford & Reynolds, 1984). Sørensen *et al* (1981) measured the duration of the fit by electromyography (EMG) and simultaneous EEG recording. Both were effective methods. The duration of convulsive activity on EMG recorded from the calf averaged 68% of the duration measured by EEG; when recording from the masseter muscles the corresponding figure was 89%.

A simpler solution was suggested by Addersley & Hamilton (1953): a sphygmomanometer cuff inflated round one arm to above systolic pressure prevents muscle relaxant injected into the other arm from reaching the muscles of the cuffed arm, which then shows unmodified movements during the fit. This technique was studied again by Fink & Johnson (1982), who compared the cuff method with EEG recording. The results were highly correlated, although the cuff estimates were 10% shorter, and they recommended the cuff technique as a valuable simple addition to standard clinical practice. All these authors implied that without a monitoring aid it was difficult to be sure that a bilateral convulsion had occurred. From past experience we held the view that there was usually no difficulty as long as the anaesthetist was prepared to vary the dose of muscle relaxant.

Method

The starting point of a fit cannot be determined clinically. All patients undergoing ECT demonstrate a tonic contraction when the electrical stimulus is passed, but this may be followed by an early or delayed start to the clonic phase. The starting point was therefore taken as the termination of the electrical stimulus. The endpoint was taken to be the cessation of clonic movements.

The treatment technique employed was routine on the unit at the time. All patients had fasted, but atropine was not given. Methohexitone (30–60 mg, i.v.) was followed by suxamethonium chloride (20–100 mg). Doses depended on age, sex and body build, and were modified in the light of the response at each treatment. Patients were gently hyperventilated with oxygen until relaxed. Brief pulse square wave stimuli were then applied from an Ectron Constant Current apparatus (1.5 ms, 40/s for 6 s at 850 mA nominal). Treatments were usually administered three times per week.

In 100 consecutive treatments involving 25 patients, a sphygmomanometer cuff was applied to the patient's upper arm and inflated to 40 mmHg above current systolic blood pressure. Anaesthetic and muscle relaxant were then immediately injected into the other arm. In any individual patient the cuff was applied alternately to the right and left arm. The doctor administering the ECT was asked to observe the whole body, and timed the fit with a stopwatch. One of us (PCB) timed both the fit duration in the cuffed arm and fit duration in the rest of the body. Seventy-nine stimuli were bitemporal, and 21 unilateral treatments were given using the temporo-parietal placement of Lancaster *et al* (1958). The majority of patients were suffering from depressive illness, and concurrent antidepressants, tranquillisers and benzodiazepine hypnotics were given.

Results

In only one treatment did a clearly visible bilateral convulsion fail to occur with a single stimulus application. The distribution of fit durations was smooth and slightly skewed (5th percentile 13 s, median 27 s, 95th percentile 59 s). Fit duration as measured by two observers regularly corresponded to within a few seconds (mean signed difference 0.26 s shorter for the doctor administering the treatment, s.d. 2.4, $P=0.28$, paired t-test). In 49 treatments the duration of the fit seen in the cuffed arm was shorter by 1–20 s than the duration of movements elsewhere in the body; in 45 treatments the duration was the same, and in 6 it was greater by 1–10 s. The clonic movements tended to persist longest in the face. On two different occasions in the same patient on bilateral treatment the cuffed arm showed no movement at all. Some of the longest fits were in patients on unilateral treatment, and the duration was similar whether the cuff was on the right or left arm.

Discussion

These results support the contention that clinical observation alone is adequate for monitoring the fit during ECT provided that the dose of muscle relaxant is not excessive. A record of the duration of the fit proves that it was at least closely observed, and may have prognostic value. The duration may be underestimated if the face is covered by an oxygen mask during the fit. It is of interest that fit duration measured in the cuffed arm was on average about 10% shorter than in other parts of the body: the same difference noted by Fink & Johnson (1982) when comparing the cuff technique with EEG recording. This may be because the fit is genuinely shorter in the cuffed arm, or because the arm becomes paralysed during the fit. The EMG findings of Sørensen *et al* (1981) support the former explanation, but Holst-Larsen (1976) has shown that suxamethonium persists in the circulation for several minutes in concentrations sufficient to cause paralysis, and during the fit violent muscular movements and increased blood pressure are likely to force blood into the cuffed arm however high the inflation pressure in the cuff. The cuff technique is therefore useful for confirming the occurrence of a fit, but may not reliably indicate its duration. It can be used as a guide to dosage of anaesthetic and muscle relaxant: an inadequately anaesthetised patient may make purposive movements with the cuffed arm, and if the dose of muscle relaxant is too large there may be movements of the cuffed arm but none elsewhere. Once the anaesthetist is working within the appropriate dose range the clonic movements which indicate a fit should be obvious without special aids. Their duration will give a good indication of the duration of convulsive activity in the brain, and if they are absent it should be assumed that a fit has not occurred.

Recurrent Pseudocyesis and Hypomania

The case of a young woman presenting with three distinct episodes of pseudocyesis occurring concurrently with annual hypomanic illness is described, and the association between pseudocyesis and affective disorder discussed, with regard both to possible underlying psychopathology and to previously proposed psychoneuroendocrine mechanisms.

The term pseudocyesis, to describe the condition in which a woman believes she is pregnant and develops somatic manifestations of pregnancy, was introduced by Good (1823). The condition has been discussed, however, by Hippocrates (1839), who described 12 women "who imagine they are pregnant seeing that the menses are suppressed and the matrices swollen". Hardwick & Fitzpatrick (1981) have emphasised the need to distinguish pseudocyesis from delusional pregnancy, simulated pregnancy, or pseudo-pregnancy caused by an endocrine-secreting tumour such as the galactorrhoea-amenorrhoea-hyperprolactinaemia syndrome (Martin *et al*, 1977). Bivin & Klinger (1937) compiled data on 444 cases drawn from 20 countries and dating back to the 17th century; they reported that in 5% of cases there was at least one recurrence of the condition.

During the past 40 years pseudocyesis has been described under a variety of nosological categories (Cohen, 1982). Brown & Barglow (1971), commenting on the links between depression and alteration in gonadal function mediated through psychoneuroendocrine mechanisms, regarded pseudocyesis as an affective equivalent; they suggested that a specific type of depression may lead to pseudocyesis in individuals with a psychosomatic specificity or predisposition. Starkman *et al* (1985), however, found no consistent linkage between psychiatric and neuroendocrine abnormalities in pseudocyesis. Some form of loss may be an important factor in the subsequent development of pseudocyesis; this may be loss of love, of a love object, of self-esteem, or of fertility (Lapido, 1979). Barglow (1966) and Barglow & Brown (1970) have reported two cases in which a loss precipitated severe anxiety and subsequent psychosis and in which pseudocyesis seemed to be a restitutive factor. We report here an unusual case in which there has been an association between recurrent hypomania and pseudocyesis on three occasions.

Case report

K is a single, unemployed girl, aged 21; she was brought up in London and is of English parents. Her parents separated when she was seven years old, and she subsequently lived with her mother who, during this period, abused drugs (in particular amphetamines) and took frequent overdoses. Her mother later remarried, and had two more children before the dissolution of her second marriage. K has one older brother, to whom she is close, but described feeling envious of the attention he received from their father during childhood. She was denied access to her father during much of her childhood; the father remarked that "K never had a childhood of her own". He had been treated for mild depression as a young man, but was never admitted to hospital; there was no other clear family history of psychiatric illness.

K was described as an intelligent girl, but failed to sit 'O' levels as a result of anxiety symptoms. She left school at the age of 16, and at first lived with her father. For a year she worked as a secretary for a Government training scheme, and then in a school for maladjusted teenagers; the latter job ended when she developed anorexia nervosa and depressive symptoms and was admitted to a psychiatric unit. Since then she has been unemployed, except for brief periods of shop or receptionist work.

Her menarche occurred at the age of ten. She described having been raped at the age of 12 by a boy in his late teens; her relationships have been greatly disturbed, and she has been unable to establish lasting friendships. However, she leads an active sexual life and had an intra-uterine device (IUD) fitted three years ago. She has never been pregnant.

Following the deaths of her grandfather and a boyfriend, she was admitted to hospital in a florid hypomanic state at the age of 18. At this time, she had her first episode of pseudocyesis. She was noted to be heavily made up, overactive, elated, and sexually disinhibited. She displayed pressure of speech and flight of ideas, and was uncharacteristically irritable. She claimed to be 22 weeks pregnant, and refused to accept the finding of a negative pregnancy test. Her abdomen was grossly distended, and she described 'heaviness' in her breasts. She was noted to have had amenorrhoea for two months and galactorrhoea prior to her receiving any major tranquillisers. Physical examination and tests, including a screen for drugs, were negative. After ten weeks in hospital, where she was treated with haloperidol, and following an ultrasound scan which showed no uterine enlargement, she gradually accepted that she was not pregnant, but persisted in the belief that she had had a miscarriage. She appeared distraught that she was not pregnant, but denied that she had really wanted a baby. Her menstrual periods spontaneously returned and her abdomen gradually reverted to its normal dimensions, before the galactorrhoea stopped.

One year after the first episode K was readmitted to the ward, having been acting aggressively at the hostel where she had been living. She presented with a further episode of pseudocyesis, and in view of her florid hypomanic state and inability to accept hospital care was placed under Section 25 of the 1959 Mental Health Act. Her progress and recovery were similar to the year before, with the exception that she was able after some time to accept that she had had a 'phantom pregnancy'.

Following discharge she lived with her father and his common-law wife, the hostel having refused to accept her back. She spent much of her time in squats with friends, and was noted to have 'mainlined' amphetamines on two separate occasions without displaying any subsequent hypomanic symptoms. She regularly attended the outpatient department and also continued in regular counselling with the psychiatric social worker. She agreed to undergo lithium therapy, and regular serum level testing indicated her compliance. One year after her second hypomanic illness, and four months after commencing lithium, she developed a third hypomanic episode accompanied by pseudocyesis. There were no clear precipitants for this admission. There was no evidence of drug abuse in the six months prior to admission. At first, she was irritable; her periods stopped and her abdomen distended. She went to Ireland on holiday, and was compulsorily admitted to a hospital there, before being transferred back to our care. On admission she remained clearly hypomanic, and had to be compulsorily detained. She had florid symptoms of pseudocyesis, including galactorrhoea and oedematous ankles, but retained some insight and accepted she had a 'phantom pregnancy'. She was treated with haloperidol, and her mood settled over a period of several weeks, accompanied initially by a return of her menstrual periods and the deflation of her abdomen, and followed by the cessation of galactorrhoea. She was ambivalent about her wishes to have a baby: she denied being disappointed at not being pregnant and desiring to have a baby, but at times requested the removal of her IUD, saying she might like to have a baby the following year.

Discussion

K's history of emotional deprivation, leading to the subsequent development of a personality characterised by a strong craving for affection and attention, resembles the personality profiles of previously reported cases of pseudocyesis (d'Orban, 1982; Hardwick & Fitzpatrick, 1981). The psychopathology of pseudocyesis bears some resemblance to that described in anorexia nervosa (Bruch, 1973); the women concerned often have high dependancy needs and display feelings of personal ineffectiveness. In fact, K did develop anorexia nervosa prior to her first episode of pseudocyesis. The onset of mania and pseudocyesis appears to have been precipitated by the deaths of her grandfather and boyfriend. Brown & Barglow (1971) suggest that "such a loss may trigger a host of defensive and regressive phenomena or multiple affects and symptoms"; they also suggest that pseudocyesis be viewed as a depressive equivalent. A phantom pregnancy may therefore provide a means of compensating an individual with pre-existing strong dependency needs who has further decompensated through some form of loss. The association between mania and pseudocyesis in our case highlights the difficulties in distinguishing between depression and defences against depression. Mania itself has also been considered by some workers to be a defence against intolerable depression.

There is no clear evidence that either 5-hydroxytryptophan or catecholamine systems are changed in 'opposite' directions in mania and depression respectively, although some evidence suggests that these illnesses show some similarities biochemically (Green & Costain, 1981). Brown & Barglow (1971) suggest that the sequence of changes in pseudocyesis may be precipitated by alterations in availability of biogenic amines at the median eminence, eventually leading to alterations in ovarian function. They suggest that these physiological changes may be induced by psychological factors, mediated through alterations in the neuronal networks connecting the higher brain centres with the median eminence of the hypothalamus. Schildkraut *et al* (1967, 1977), in their comprehensive reviews of the literature, suggest that some depressions may be associated with a functional deficiency of noradrenaline at specific receptor sites in the brain, whereas elation may be associated with an excess of amine.

The finding of mania in association with pseudocyesis therefore makes the hypothesis that pseudocyesis is specifically related to a reduction in availability of biogenic amines at neuronal receptor sites less likely, unless there is a subgroup of individuals who have a deficiency of noradrenaline at these sites, and not an excess as previously suggested.

Seasonality, Birth Complications and Schizophrenia in a High Risk Sample

It has been suggested that viral infections, more prevalent in the winter months, might increase pregnancy and birth complications, which might in turn be responsible for the excess of winter-born patients with schizophrenia. In this study it was found that the rate of schizophrenia among high risk winter-urban births who had suffered a perinatal complication was significantly greater than that for those who had not, thus supporting the hypothesis.

Births occurring in winter months have been shown to produce a slight excess of later-diagnosed schizophrenics. These findings have been quite robust, as evidenced by the convergent data from large population studies (reviewed by Dalén, 1975) and from samples drawn from countries in southern, tropical, and northern latitudes (Dalén & Roche, 1975); Parker & Neilson, 1976; Parker & Balza, 1977). This has led to the hope that an understanding of this relationship might suggest an aetiological hypothesis for some subgroups of schizophrenia. In the light of some suggestive findings (including the greater winter prevalence of viral infections), it has been proposed that viral infections might be involved in the aetiology of some forms of schizophrenia (Torrey, 1980).

In a longitudinal and prospective, high risk study (the index children have mothers with severe and chronic schizophrenia, and thus are at high risk for schizophrenia themselves), the degree of genetic risk and indicators of viral infection interacted to predict later schizophrenia (Machón *et al*, 1983; Mednick & Schulsinger, 1968). It was hypothesised that certain birth conditions (winter and urban birth) would increase the likelihood of contracting a viral infection. Genetically vulnerable individuals born in winter and in an urban environment should be more likely as foetuses or neonates to have suffered some central nervous system damage due to the infection; the effects of the infection would manifest themselves in a higher likelihood of psychological impairment, including schizophrenia. The highest rate of schizophrenia was observed in the high risk urban-winter birth condition (21%); the high risk base rate was 9%.

Videbech *et al* (1974) demonstrated that the increase of later-diagnosed schizophrenics among those born in the winter is strongly paralleled by a winter increase in still-births in the general population. They suggested that both of these effects might be produced by increased levels of pregnancy and birth complications during winter. Wrede *et al* (1980) provided supporting evidence: in a representative Finnish population of offspring of schizophrenic mothers, the high risk children had significantly more pregnancy and birth complications (PBCs) than the controls. These differences were almost entirely explained by the large number of PBCs in the winter-born high risk children.

Parnas *et al* (1982) reported that among high risk subjects, those who were later diagnosed schizophrenic had the most severe and the greatest number of PBCs. These findings are consistent with those of McNeil & Kaij (1978), who found increased levels of birth and neonatal complications among process schizophrenics. Within the context of a stress-diathesis model, the disadvantage posed by PBCs has been theorised as representing at least one important class of environmental stressors which interact with a genetic predisposition to increase the likelihood of later adult schizophrenia (Parnas *et al*, 1982; McNeil & Kaij, 1978). Based on these suggestive findings, additional analyses to examine the effects of PBCs were carried out on the data from the Machón *et al* (1983) study. It was hypothesised that foetal viral infections might be responsible for the increased level of PBCs observed in schizophrenia. PBCs might then be seen as a factor which mediates the relationship between the effect of winter and urban birth and subsequent development of schizophrenia.

Method and results

It was hypothesised that among high risk winter-urban born subjects, the highest rates of schizophrenia would occur among those with pregnancy and birth complications. The assessment of PBCs was as described in Parnas *et al* (1982). The results of the present analyses are presented in Table I.

The rate of schizophrenia among the HR subjects born in winter and in an urban area with pregnancy and birth complications is 30%. This figure represents an increase of 42% (from a rate of 21% to a rate of 30%) in the rate of schizophrenia when the dimension of pregnancy and birth complications (as measured by absolute number of complications) is introduced to the high risk winter-urban birth condition (see Appendix 1). Among the high risk urban births with PBCs there were a disproportionate number of schizophrenics born in winter months (30%) compared with those born in non-winter months (9%) (Fisher's Exact Test, $P<0.04$, one-tailed). These results were identical across the other two dimensions of PBCs: the most severe complication score (Fisher's Exact Test, $P<0.02$, one-tailed) and the weighted sum of complications score (Fisher's Exact Test, $P<0.025$, one-tailed). Among the high risk urban births with no complications, the rates of winter born schizophrenics (9%) were not significantly different from the non-winter born (7%) (Fisher's Exact test, $P<0.50$, one-tailed).

TABLE I

Rate of schizophrenia among high-risk subjects, distributed according to place and season of birth and to presence or absence of PBCs[1]

	Urban birth		*Not-urban birth*	
	Winter	*Not-winter*	*Winter*	*Not-winter*
PBC	30% (6 of 20)	9% (4 of 44)	0% (0 of 2)	10% (1 of 10)
No PBCs	9% (1 of 11)	7% (4 of 55)	0% (0 of 10)	0% (0 of 14)

[1] Only 16 of the 17 consensus-diagnosed schizophrenics reported in Machón *et al* (1983) are included in this analysis; one, belonging to the Not urban-Not winter cell, was dropped from the analyses due to incomplete PBC data. Of non-schizophrenics, the following numbers of subjects were dropped from each cell due to missing PBC data: respectively 2, 13, 7 and 17.

The observed and expected cell frequencies for the 'not urban birth' group in Table I are small, and so meaningful statistics were not feasible for these two sets of analyses given that only one person (out of 36) developed schizophrenia.

Individual pregnancy and birth complications (as opposed to the summed and scaled scores used above) were also examined. Analyses with these scores were not feasible, however, due to the small number of subjects in the respective cells.

Discussion

The presence of PBCs among the high risk winter-urban births appears to be associated with an increased probability of later adult schizophrenia. These data suggest that the relationship between the high risk urban-winter birth condition and subsequent schizophrenia might be mediated by the presence of PBCs in the gestational periods and deliveries of these individuals. There are several plausible interpretations of these findings. One might be that PBCs are related to winter births and that these in turn produce subtle brain damage, which later results in psychological impairment. A second interpretation might be that viral infections lead to increased levels of PBCs, which in turn damage the foetus and predispose the individual to schizophrenia. A third interpretation might be that the perinatal viral infection (or some unknown seasonal factor) directly attacks the central nervous system and as a side-effect increases PBCs. It is impossible to provide a test of these alternative explanations with these data, since no specific information on viral infections is available. Further research is needed to elucidate the nature of the relationship between perinatal viral infections and PBCs, as these might relate to subsequent adult schizophrenia.

The Continuum of Psychosis and the Gene

SIR: Owen & Nimgaonkar (*Journal*, April 1987, **150**, 566–567) give reasons why they are persuaded by some of the arguments (Crow, *Journal*, October 1986, **149**, 419–429) for a continuum concept, but do not accept that this reflects on the genetic basis of the recurrent psychoses. The points they raise illustrate some of the issues at stake between the 'classical' Kraepelinian view and a continuum theory.

In stating that none of the studies that show an excess of individuals with schizophrenia among the offspring of patients with affective disorder "employed modern diagnostic criteria" Owen & Nimgaonkar draw attention to a bias intrinsic to most investigations of the genetics of psychosis – the tendency to exclude cases which do not meet a particular preconception of the nature of the disease under investigation. Thus adherents of the Kraepelinian viewpoint have seized eagerly upon DSM-III and similar diagnostic decrees as an opportunity to purify their index samples of 'typical' affective or schizophrenic psychoses. In so doing they eliminate the intermediate states which in my view are the key to the problem. One of the points I made in my paper was that even when DSM-III criteria are adopted (as in the recent studies of Gershon *et al* of affective disorder and Kendler *et al* of schizophrenia) a substantial excess of cases with 'schizoaffective' disorder is seen among the relatives of patients with both prototypical psychoses. According to one's viewpoint these cases represent 'diagnostic error' or evidence for a continuum. When DSM-III criteria are applied they are excluded. Thus the bias inherent in a classical Kraepelinian perspective is further accentuated by application of criteria which are founded on the binary concept.

The point is illustrated by Owen & Nimgaonkar's reference to the work of Elsasser on the children of two psychotic parents. The combined results of Elsasser, Schulz and Kahn are shown in Table I.

Owen & Nimgaonkar quote the rates of illness in the children of parents with manic-depressive and schizophrenic illnesses. However, Elsasser also included a category of "atypical psychosis". Since this

TABLE I

The children of two psychotic parents[1]

No. of parental pairs	*Parental mating*[2]	*No. of children over 16*	*Psychotic children*[3]							
			S		*M*		*A*		*? Nature*	
			a	*b*	*a*	*b*	*a*	*b*	*a*	*b*

21	A×M	55	–	–	4	2	4	1	–	–
17	A×A	67	5	–	5	1	10	1	–	2

1. Adapted (the rates of non-psychotic disorders are excluded) from Table 12 of Slater & Cowie (1971).
2. S = schizophrenic, M = manic-depressive, A = atypical.
3. a = diagnosis certain, b = diagnosis uncertain.

category includes 78 (29%) of the total of 268 parents it is not of marginal significance. Among the offspring of the schizophrenic and manic-depressive matings one atypical and two psychoses of uncertain nature were recorded in addition to more typical schizophrenic and affective illnesses. Of more interest is the fact that among the offspring of manic-depressive/manic-depressive matings were observed two cases of atypical psychosis and one of definite schizophrenia, and among the offspring of atypical/atypical matings were observed five certain and one doubtful manic-depressive psychoses, 10 certain and one doubtful atypical psychoses and five definite schizophrenic psychoses. The pattern of transmission appears more complex and the separation between the prototypical psychoses much less clear when atypical psychoses are included.

There is no alternative to confronting the question of the genetics of schizoaffective psychosis. Angst *et al* (1983) have collected more information on this topic than any other group: "The underlying hypothesis of a continuum of psychoses from depression to schizophrenia is not disproved by our results. They show that on a descriptive level of symptoms and syndromes, taking into account the whole course of psychosis, the dichotomy into schizophrenic and affective psychosis is highly questionable. We do not only find transitional groups of schizoaffective patients but also marked affective symptomatology underlying or superimposed on schizophrenia".

An earlier study by Angst *et al* (1979) is relevant to Owen & Nimgaonkar's belief that schizoaffective disorder is no more than a result of the coincidence of schizophrenia and affective disorder in the same family. In 71 of these 150 cases of schizoaffective illness at least one other family member was affected with schizophrenia (S), schizoaffective (SA) disorder or affective (A) (unipolar or bipolar) illness. In only 17 (i.e. a minority) of these 71 families were the illnesses in the secondary cases placed in more than one category (S, SA or A) and in only eight cases did these include schizophrenia and affective disorder. Interestingly, affective disorder was found more frequently than schizophrenia (23:11) in parents of schizoaffective probands, whereas schizophrenia was slightly more frequent (11:13) in siblings. This is compatible with an inter-generational shift along the continuum.

It is little recognised that Kraepelin (1920) himself had doubts about the binary concept: "Perhaps it is... possible to tackle the difficulties which still prevent us from distinguishing reliably between manic-depressive insanity and dementia praecox. No experienced psychiatrist will deny that there is an alarmingly large number of cases in which it seems impossible, in spite of the most careful observation, to make a firm diagnosis... Nevertheless it is becoming increasingly clear that we cannot distinguish satisfactorily between these two illnesses and this brings home the suspicion that our formulation of the problem may be incorrect".

Thus Kraepelin himself was apparently abandoning the position which Owen & Nimgaonkar are defending.

AIDS Panic

Sir: Jacob *et al* (*Journal*, March 1987, **150**, 412) report on five male patients with 'AIDS phobia'. Generalisations based on small numbers need to be interpreted with caution. Since 1984, we have systematically assessed all patients who were referred to psychiatric services with a clinical picture of panic disorder and a prominent fear of having developed AIDS but were negative for HTLV-III antibodies. Our findings are at variance with those reported by these authors. Of 24 patients in our sample (mean age 38.2 years; range 22–61; 14 females) only four admitted to being bisexual; all the rest were heterosexual. A majority (20) described a recent psychological precipitant, not always of a sexual nature; the latter was discovered in 14 patients, 10 of whom admitted to a recent illegitimate or 'unusual' sexual relationship and 4 to a homosexual contact. A detailed chronological catalogue of media reports was compiled, and an overlay plot of case inceptions showed that although a few cases did occur soon after a major media publicity campaign on AIDS, there was no significant correlation for the sample as a whole.

The mean duration of symptoms before presenting to psychiatric services was 4.5 weeks (range 3–8), and the total duration of symptoms was 6.2 weeks (range 3–22). The premorbid personalities of patients included obsessional (8), anxious/hysterical (6) and others (6); and in the rest we could detect no abnormality. Only half the patients had some form of mental disorder: obsessive-compulsive disorder (4), depressive illness (2), schizophrenia (2), and various anxiety syndromes (4), including panic disorder.

The clinical course varied considerably: less than half (11) showed complete remission of symptoms after simple reassurance or a couple of sessions of supportive therapy. At the end of three months, only five patients had persistent symptoms of AIDS panic. The most distressing symptoms were severe anxiety syndromes and depression (suicidal symptoms in five), and in four there was evidence of delusions or hallucinations. Seven patients required no specific treatment apart from reassurance in the out-patient clinic, 11 were seen regularly for supportive therapy, seven received benzodiazepines, two antidepressants, and two neuroleptics.

Detailed analysis has been submitted for publication, but the findings described above show that AIDS panic has a more complex aetio-pathogenesis than that suggested by Jacob *et al.* It illustrates the dangers of making sweeping generalisations about clinical phenomena which have many and varied contributions from constitutional as well as environmental factors.

Not a Case of Pseudo-AIDS

SIR: *Case report.* A 30-year-old married serviceman presented with the complaint that he believed that he had AIDS. He had no previous psychiatric history and presented to his GP complaining of vague physical symptoms which he ascribed to AIDS. He denied any homosexual contact or any heterosexual contact outside marriage. He claimed that he had been exposed to risk of infection with the human immuno-deficiency virus in a fight with an unknown assailant. The history was not suggestive of AIDS, and there was no clinical evidence of the syndrome. Despite reassurance he presented on several further occasions with the belief that he had AIDS. He was therefore eventually referred for AIDS counselling and testing.

While awaiting counselling the patient again presented to his GP and on this occasion admitted to symptoms of depressive illness with lowered mood, sleep disturbance, loss of interest, and tearfulness. His GP made a diagnosis of depressive illness and started treatment with doxepin. Approximately one week later the patient's mood appeared to be lifting. He did not appear over-concerned about AIDS. However, before the negative results of testing were received, the patient hanged himself, having put his affairs in order and having taken precautions against discovery.

This patient was managed by his GP, who made a diagnosis of depressive illness and initiated treatment with antidepressants. Unfortunately the patient killed himself early in treatment. The point in question is the significance of the initial presenting symptoms of fear of AIDS and whether this man represented a case of 'pseudo-AIDS' as described by Miller *et al* (*Journal,* May 1985, **146,** 550–551).

Miller presented two cases of pseudo-AIDS, one with an anxiety neurosis and one with a depressive illness. It has long been recognised, however, that the content of psychopathology can be influenced by current themes. What is important in patients who present with concern about AIDS in the absence of the disease is not so much AIDS, but the underlying illness which gives rise to the symptoms. We should concentrate not on the question of AIDS, but on making the correct diagnosis. The significance of the presenting symptom of worries about AIDS is not that there is a specific pseudo-AIDS syndrome but that we should be aware that we may see large numbers of patients in whom AIDS figures as the content of the phenomenology. This is not something which is specific to AIDS, but is a result of the fact that AIDS is the most important new disease which we have to face in this century and is a major part of the public consciousness at this time, being prominantly portrayed in the media. We need to be aware, not only that the fear of AIDS may give rise to psychopathology, but, perhaps more importantly, that the psychopathology of illness may be coloured by the collective fear of AIDS which exists and which is likely to grow in the wake of the government's publicity campaign. We are likely to see patients who are suffering from a wide variety of psychiatric illnesses all presenting with worries about AIDS.

Miller states that there is a clear need for clinicians to be alerted to the likelihood of psychiatric complications arising from fear of AIDS in their homosexual patients. It appears likely that this advice is correct, but already out of date in one important aspect: AIDS is no longer purely a disease of homosexuals and drug addicts. Growing numbers of cases are arising as a result of heterosexual transmission. It is important that we remember that a wide range of psychiatric illnesses in heterosexual patients may also present with fear of AIDS.

The Burden of Care: The Impact of Functional Psychiatric Illness on the Patient's Family

Sir: This article (Fadden *et al, Journal,* March 1987, **150,** 285–292) purports to review the literature on "the effect of severe mental illness on other members of the patient's family", but at no point mentions the word 'child'. Most definitions of 'family' include a reference to children, for example, "the household, or all those who live in one house (as parents, children, servants): parents and their children: the children alone" (Macdonald, 1972).

A number of authors have written about the impact of parental psychiatric illness on children. Rutter & Quinton (1985) found that these children had a higher rate of psychiatric disturbance than a comparison group, were more likely to experience discord, and were often exposed to hostile or anxious depressed behaviour. Rodnick & Goldstein (1974) studied maternal behaviour before and after schizophrenic breakdown and commented that even in those mothers with good premorbid functioning, the recovery of 'mothering function' was delayed for as long as six months after discharge from hospital. Significant intellectual deficits have been found in children whose mothers were depressed during their first year (Cogill *et al,* 1986). There is no doubt that some children are adversely affected by a parent's mental illness.

Fadden *et al* comment on the "high rates of divorce and separation in marriages where one patient [I presume they mean partner] is mentally ill." Wallerstein & Kelly (1976), among others, have examined the effects of divorce on children. Again, there is no doubt that some children suffer.

The link between parental psychiatric problems and emotional disturbance in children is not necessarily, or always, causative. It does exist. We must be aware that the children in families where a parent has a functional psychiatric illness are at risk.

Behavioural Neurology

Sir: Reynolds, in his book review (*Journal,* March 1987, **150,** 421–422) asks the interesting question, "What is behavioural neurology?". I too have sought to discover the origins and boundaries of this discipline, and am usually led back to the writings of Geschwind and his colleagues. As Reynolds points out, behavioural neurology has rediscovered many of the localised neuropsychological syndromes described by the neuropsychiatrists of the late 19th century, and essentially attempts to understand disturbances of behaviour following identifiable brain lesions. The culmination of this line of thinking was represented by Geschwind's (1965) classic paper on disconnection syndromes. As such, behavioural neurologists are found largely in the USA and approach behavioural problems from a relatively strict localisationalist, neurological point of view.

This may be contrasted with the related discipline of neuropsychiatry, where holism and integration of cerebral function tend to be stressed. Neuropsychiatry adopts a more dynamic view of the relationship between the brain and behaviour, compared with the more static models adopted by behavioural neurology (Trimble, 1981).

A third, related discipline is biological psychiatry, the boundaries of which I have discussed recently (Trimble, 1987). Biological psychiatry attempts to understand psychopathology in relationship to underlying disturbances of brain function, and concentrates more on primary psychiatric conditions such as affective disorder and psychoses than either neuropsychiatry or behavioural neurology.

Finally, organic psychiatry examines "cognitive, behavioural and emotional consequences of cerebral disorder" (Lishman, 1978), which includes not only the consequences of structural brain disease, the field of behavioural neurology, but also metabolic, toxic and other systemic conditions which disrupt cerebral function and may provoke psychopathology.

The recent growth of interest in three of these disciplines (behavioural neurology, neuropsychiatry and organic psychiatry), all of which overlap at their boundaries, reflects the long overdue interest in the neglected disorders which form the hinterland between neurology and psychiatry. Furthermore, it represents attempts by their practitioners to integrate the fields of psychiatry and neurology, which have become too divergent.

Reynolds notes of behavioural neurology: "it is a discipline that does not appear to exist in the UK". If the sighting of one black swan disproves the premise that all swans are white, then I submit that behavioural neurology does exist in the UK.

Prognosis of Depression in Old Age

SIR: Murphy (*Journal*, February 1987, **150**, 268) is incorrect in assuming that our mortality rate is remarkably similar to that obtained in her study. The figure of 35% she quotes for our patients refers to the entire follow-up period, which was as long as 104 months for some patients. We have already calculated the four-year rate for our cohort as part of another study (*Journal*, in press). For the 97 ascertained (three were untraceable) the deaths at four years amount to 25 (18 women and 7 men), i.e. 26%. It is usual to assume a year-on-year rate of 5% for this age group, or 20% at four years – not much different from our findings and in marked contrast to the 37% quoted by Murphy for her study. Thus, the difference in death rates between the two cohorts of patients that was evident at one year seems to persist at four-year follow-up.

This is certainly not the only difference identified, but it is the one that most robustly withstands arguments about the validity and reliability of our data. Murphy raises doubts about these on account of our retrospective methodology, although survivors were interviewed and information from GPs and, in some instances, personal contacts was collected for others. In fact, she too used a retrospective method for her own assessment of the course of depressive symptomatology, and unless patients are interviewed by a researcher extremely frequently it is hard to see how it can be otherwise.

We have attempted some replication of Murphy's work and found concurrence over major life events and physical ill-health, but not with regard to the prognostic significance of severity of depression and delusions. However, we have also hopefully widened the area of research. Hence, Post's four-fold categories of outcome were used not only to replicate his work, but also because a dichotomous 'good' versus 'poor' approach conceals significant differences in the quality of mood during life – something we believe to be immensely important. Also, we have specified the range of treatments and after-care offered, since they can hardly be discounted in assessing outcome.

It is hoped that future research can synthesise the different emphases in these studies, so that at least we are drinking from the same pint pots!

Present State Examination Change Rating Scale

SIR: The inter-rater reliability of the ratings is impressively high (*Journal*, February 1987, **150**, 201–207), but reassurance is necessary on several points.

Are not the intra-class correlation coefficient, with its significance tested by the '*F*' statistic, and the Pearson product-moment correlation coefficient not parametric statistics, and if so why have the authors chosen to use these in the absence of evidence that the underlying scale of measurement has interval qualities? The PSE rating scale of 0, 1 and 2 is at best ordinal, being a set of ranks separated by unequal intervals, so how plausible is it to assume that a symmetrical bell-shaped curve arises out of such a scale? Would not the conservative use of non-parametric statistics be preferable?

Do the intra-class correlation coefficient and the Pearson product-moment correlation coefficient allow for agreement due to chance: thus, has such agreement been subtracted from the observed coefficients?

Do the intra-class correlation coefficient and the Pearson product-moment correlation coefficient distinguish between agreement and association? Agreement is a special kind of association of interest in reliability studies, and it is possible for association to be very high while agreement is poor.

Would the authors like to say why they did not place screens between the raters? This strategy would have made the authors' claim that the raters were independent more credible, because they would have been seen to acknowledge the possibility that raters can make inferences about one another's rating behaviour by noting when pen moves to paper. Placing a screen between raters has been shown to result in a fall in the very high agreement about symptoms in joint interviews to the level for independent interviews (Robinson *et al*, 1982), which raises the intriguing possibility that this very high agreement reported here and elsewhere, for example in the International Pilot Study of Schizophrenia (World Health Organization, 1973), has at least two components: one a measure of agreement about symptoms by psychiatrists, the other a measure of sensitivity between psychiatrists.

Folate, Vitamin B_{12} and Posture

SIR: Abou-Saleh & Chung-A-On (*Journal*, January 1987, **150**, 133) have reported a study of vitamin B_{12} and folate plasma levels.

We observed in 23 patients who had been lying down for at least 6 hours, that standing for 30–40 minutes increased vitamin B_{12} and folate plasma levels by more than 10%. Red cell folate levels decreased non-significantly by an average of approximately 2%.

The explanation of our observations is the following: as soon as the subject stands, fluid (up to 23% of plasma volume) leaves the circulation under the influence of hydrostatic forces, particularly in the lower limbs. As a result, there is an increase in concentrations of blood constituents such as red cells, proteins (Fawcett & Wynn, 1960; Hagan *et al*, 1978), and protein-bound substances such as calcium (Husdan *et al*, 1973), folate, and vitamin B_{12}, which do not readily pass through the capillary membrane. Hagan *et al* (1978) have shown that standing for 35 minutes increases venous haematocrit, haemoglobin, and plasma protein levels by 10%, 10%, and 20% respectively.

Our observations underline the need to control posture and other factors which may change plasma volume (Husdan *et al*, 1973; Abalan *et al*, 1987) in folate and vitamin B_{12} plasma level studies as in studies of other protein-bound vitamins.

Transient Effect of Diazepam in Some Sub-acute Organic States

SIR: Aynsworth's report (*Journal*, January 1987, **150**, 110–112) of a patient with a catatonic state possibly related to viral encephalitis prompts us to comment on her finding in that patient of a brief return to apparent normality after intravenous diazepam. We note that she quotes previous reports in which intravenous barbiturate resulted in improvement in organic catatonic states.

Case report: A 19-year-old woman suffered severe hypoxic brain damage due to drug overdose, with a severe defect in short-term memory and attention span and a trans-cortical aphasia. At times she was mute or nearly mute. Grimacing and posturing was accompanied by disinhibited behaviour and apathy. For several months she refused to eat. Intravenous sodium amytal produced a striking temporary improvement in her awareness, attention, speech, and interpersonal relationships. Oral diazepam resulted in a recordable improvement in her behaviour and level of activity over several weeks, and in a longitudinal cross-over study with placebo over several months the improvement was deemed attributable to the diazepam. Intermediate memory (recording and recall of verbally and visually represented material) improved slightly with diazepam and amytal.

We do not understand the mechanism of this finding in our patient or in Aynsworth's patient. The fact that improvement occurs in catatonic states with barbiturate or diazepam infusion should not necessarily lead clinicians to suspect hysterical mechanisms. In the female patient we report, the benefits of diazepam gradually wore off over six months. Although environmental changes have resulted in further improvements in her condition she remains in sheltered accommodation.

Similar Incidence Worldwide of Schizophrenia: Case not Proven

SIR: The article by Sartorius *et al* (*Psychological Medicine*, November 1986, **16**, 909–928) is a summation of a prodigious amount of work and contains invaluable data. The two important conclusions reached, however, must be examined closely in the light of the diagnostic criteria and population cohorts which were used.

Firstly, we consider the significance of the "central" (by which they mean 'nuclear', Schneiderian) schizophrenia syndrome that the authors state occurs with approximately equal frequency worldwide. To study incidence data, the authors include all individuals in a given catchment area who made a first lifetime contact with any helping agency, hospital, clinic, or religious or traditional healer over the one-year collection period of the study with a disorder that met either broad (ICD–9 or CATEGO S, P, O) or narrowly defined (CATEGO S+, Schneiderian, nuclear) criteria for schizophrenia. The problems with these definitions are well known: neither the ICD–9 definition nor the Present State Examination (PSE)-based CATEGO classification requires a minimum duration of symptoms for diagnosis of schizophrenia. This appears to have led to the considerable diversity of the schizophrenic samples collected in participating countries, as illustrated by the large differences in age-specific incidence rates in them. For example, in their Table 6 it is evident that the percentage of first-contact schizophrenic patients in the 15–24 age group in Cali (70.8%) is more than three times that in Moscow (21.8%). Among 25–34 year olds, Ibadan (42.3%) has twice the percentage of Cali (21.4%). For 35–44 year olds, the range is even wider: 3.6% of the sample of first contact schizophrenics in Rochester falls in this age-group, compared with 6.5% in Agra, 19.4% in Dublin, and 22.3% in Moscow. Finally, Moscow reports that 20.4% of their total sample of first-contact schizophrenic patients fell in the oldest age-group (45–54 years), while only 1.2% of first-contact schizophrenic patients in Agra and 3% of the Cali sample fell in this range – a nearly 20-fold difference.

With respect to the clinical syndrome, again the differences are as striking as the similarities: while only 26% of patients in developed countries had acute onset, 49% had such onsets in developing countries. A diagnosis of acute schizophrenic episode was made in 40% of patients in less developed countries, but only 10% in developed countries, and the catatonic subtype was 10 times more common in developing countries. Indeed, inspection of their Fig. 2 indicates that in the developing countries more than 30% of all patients in the survey had been ill less than one month and 50% for only two months! While the differences in clinical presentation, such as more violence and excitement in developing countries and more paranoia and depression from developed lands, might be attributed to cultural differences, the great differences in mode of onset and age distribution between centres indicates that the schizophrenia defined by the authors presents great differences between the places studied. Indeed, what would be designated by RDC or DSM–III criteria as *acute reactive, brief* or *schizophreniform* psychosis is characteristic of a majority of admissions to psychiatric facilities in the developing countries. If diagnosed as schizophrenia, this may lead to the false conclusion that the same disorder has an equal prevalence around the world. Clearly, inclusion of this large number of acute psychoses of less than two months' duration, predominantly from the developing countries, will also bias the statistics by indicating a more favourable course for schizophrenia in developing countries. Inclusion of alcohol and drug-related psychoses by the authors will further blur the data, and may account in part for the large differences in age of first-contact schizophrenic patients between the centres.

The incidence data, claimed to show a similarity in all populations studied, are flawed in two respects. Firstly, only 8 of the 13 areas studied had sufficient case-finding coverage and base population data to derive incidences; Ibadan, Cali, Agra, Prague, and Rochester were excluded. Exclusion of the first three means that the incidence data from developing countries derive solely from Chandigarh – a rather unique 'model city' in the Punjab and the site of one of India's major medical centres. With all of South America, Africa, and most of Asia excluded, the incidence data should not really be referred to the *worldwide* prevalence question. Secondly, the similarity of incidence worldwide which is claimed by the authors holds only for their S+ category, i.e. 'nuclear', Schneiderian schizophrenia; this category shows poor specificity, especially in early cases (Silverstein & Harrow, 1978), and very poor predictability for subsequent outcome diagnosis (Brockington *et al*, 1978). Furthermore, Schneider's first-rank symptoms are frequently found in mania, in addition to schizophrenia (Carpenter & Strauss, 1974). The S+ category is thus of doubtful validity for the diagnosis of schizophrenia. Yet it is only with this narrow, S+ definition that the author's claim of equal incidence and prevalence holds, for there is a large variation in incidence between centres with their broad (Catego S, P, O) definition of schizophrenia, with e.g. rural Chandigarh women having four times the incidence of women in Aarhus. This suggests either an epidemic-like pocket of schizophrenia in the rural Punjab, or more likely reflects the high incidence of culturally-based brief psychosis that would probably have been found in the other traditional societies, had they been included in the incidence survey.

The greater prevalence of acute reactive psychosis in developing countries has been long and widely recognised by psychiatrists working in these regions (Dembovitz, 1945; Carothers, 1953; German, 1972). During a three-month period in which JRS served as Consultant Psychiatrist at the School of Medicine of the University of Zimbabwe, it was found that more than half the patients admitted to the psychiatric ward of the Harare Hospital with a diagnosis of schizophrenia failed to meet either RDC or DSM-III criteria for duration of the illness, and that onset was often close to an emotionally traumatic event. Using DSM-III criteria, their diagnosis was acute brief or reactive psychosis (Stevens, 1987).

There is no doubt that typical schizophrenia, meeting RDC, DSM-III, Bleulerian, and Kraeplinian criteria, exists in all parts of the world where it has been looked for. In the absence of some duration criteria, however, the greater incidence of acute, reactive, culturally-based psychoses in developing countries is likely to make an important contribution to the conclusion by the authors that schizophrenia has a better prognosis in developing countries. For the three reasons mentioned – the questionable validity of the Catego S+ category for diagnosis of schizophrenia, the exclusion of all but one developing country in the incidence study, and the inclusion of brief (including culturally-related, drug, and alcohol) psychoses in their study – the authors' conclusion of worldwide similarity of schizophrenic incidence also seems premature.

Sir: The recently released WHO multi-centre study of the incidence of schizophrenia was said by the authors to lend "support to the notion that the 'central' schizophrenic syndrome may be occurring with approximately equal probability in different populations" (Sartorius *et al*, 1986). The WHO study, however, does not shed much light on the comparative incidence of schizophrenia because all seven centres utilised in the incidence study were located in areas in which previous prevalence studies would suggest no more than a two-fold to three-fold difference; that is exactly what the WHO incidence study found.

The centres utilised in the WHO study and prevalence of schizophrenia per 1000 population reported in previous studies in those countries (Torrey, 1987) included: Nagasaki (2.1-2.3), Nottingham (2.1-3.4), Moscow (2.6-3.8), and Chandigarh (1.9-5.6 in different areas of India; no prevalence study had been carried out in the Chandigarh region). Honolulu was utilised as the American centre despite the fact that it is very atypical demographically and that previous first admission rates for schizophrenia show Hawaii to rank comparatively low among the states; by contrast New Haven, Baltimore, and St Louis were recently reported to have high prevalence rates of schizophrenia (Myers *et al*, 1984).

Aarhus was used as the Scandinavian centre; previous prevalence studies (2.7 per 1000) (Nielson, 1976) and incidence studies (Munk-Jorgensen, 1986) have shown rates for schizophrenia in Denmark to be comparatively low. By contrast, most studies in Norway, Sweden, and Finland have reported high rates, up to 17.0 per 1000 in the Book *et al* (1978) study of northern Sweden. The final centre used in the WHO study was the St Loman's case register in Dublin. In 1982 schizophrenia prevalence figures from this case register were only 1.7 per 1000 (Walsh, personal communication), less than one-third the 5.9 per 1000 rate for the County Roscommon case register in western Ireland and less than one-seventh the rate of 12.6 per 1000 reported by Torrey *et al* (1984) for a suspected high prevalence pocket in western Ireland.

In summary, the WHO incidence study of schizophrenia studied seven centres for which previous prevalence studies would lead one to expect no more than a two-to-three-fold difference in incidence. That is precisely what was found. Until a multi-centre incidence study is done utilising centres from suspected high incidence (e.g. northern Scandinavia, western Ireland) and low incidence (e.g. some tropical areas) countries it would seem unwise to regard the WHO incidence study as a reflection of worldwide incidence rates.

Psychiatrists' views on Treatment of Depression

Sir: I note Armstrong & Andrew's paper on the treatment of depression by Australian psychiatrists (*Journal*, December 1986, **149**, 742–750). This is one of many papers supported by the Royal Australian & New Zealand College of Psychiatrists under a so-called Quality Assurance Project.

The implications of this work are actually quite astounding. The modal length of treatment for each of the case vignettes is over fifteen hours per patient. Simple arithmetic would suggest that every consultant psychiatrist would have reached total saturation point with the referral of one hundred patients per annum. Quality treatment for these one hundred fortunate people would totally absorb the Quality Assured Practitioner to the exclusion of all other professional activities. This work obviously has more to do with maximising psychiatrists' incomes than with making psychiatry more available to the masses.

In Australia, I would add, this Quality Assurance Project is being held up as a model of excellence to which the College hope all psychiatrists will ultimately aspire, or should I say, conform.

'Afternoon Radiator-Sitting Syndrome': Hypothermia and Early Diagnosis of Self-Induced Water Intoxication

Sir: We report on a patient with schizophrenia and acute self-induced water intoxication (SIWI) who presented with symptoms of hypothermia. Further investigations revealed a clinical sign which may be useful in the early diagnosis of SIWI.

Case report: A 37-year-old man, who had been an in-patient for 17 years, presented at 1600 hours with complaints of feeling unwell accompanied by uncontrollable shivering, shaking, and chills. Oral temperature was 35.8°C. Over the next two hours he became increasingly confused and ataxic, and was incontinent of large volumes of dilute urine. Laboratory investigations were normal except for serum sodium which was markedly low at 121. Overnight he passed approximately eight litres of dilute urine (S.G. 1.001), and by 0800 the following morning was alert and symptom-free, with a temperature of 37°C and serum sodium of 136.

Close observation over the next two weeks revealed that he typically consumed 9–12 litres of water daily, and dropped his sodium from a morning value of 136 to a mid-afternoon value of 126–128, accompanied by recurrent, but less severe, symptoms of hypothermia. Regardless of ambient temperature, he wore several sweaters and jackets and spent much of the afternoon sitting beside, or on, the hot water radiators which supplied heat to the building. Interviews with nursing staff who knew the patient well revealed that this was his 'typical' behaviour pattern, which had been present for many years. With fluid restriction to 3–4 litres a day this pattern disappeared, and his afternoon sodium values returned to normal.

Seven additional patients with a similar pattern of afternoon radiator-sitting syndrome were identified in a single afternoon by a visual survey of five chronic psychiatric wards involving 210 patients. On further investigation, all seven showed polydipsia and recurrent afternoon hyponatraemia (sodium levels of 124–132). In each case, fluid restriction abolished the afternoon hyponatraemia and radiator-sitting behaviour. Four patients had no previous known history of hyponatremia or polydipsia. One later developed hyponatraemic seizures. Three had previous episodes of acute water intoxication with hyponatraemia and seizures. Chart reviews of these three revealed numerous descriptions of what appeared to be, in retrospect, afternoon hypothermia, dating as far back as 14 years prior to the onset of seizures and formal diagnosis of water intoxication.

The recurrent afternoon hypothermia and hyponatraemia associated with polydipsia in these patients may be related to volume overload with tapwater at room temperature, faster than it can be heated or cleared. Alternatively, the altered temperature regulation, increased thirst, impaired water homeostasis and circadian rhythmicity may all be secondary to increased hypothalamic dopamine activity and may represent a tardive hypothalamic syndrome.

Self-induced water intoxication typically goes unrecognised until the development of episodes of acute intoxication with severe neurological symptoms which may be life-threatening (Ferrier, 1985). Additionally, it may be related to tardive changes in hypothalamic dopamine function (Jones, 1984). Early diagnosis is therefore crucial. Screening for afternoon radiator-sitting syndrome appears to be a rapid, inexpensive, sensitive, and, thus far, specific way of detecting patients at risk for this disorder.

A Search for Sub-Clinical Arteriosclerotic Dementia

SIR: McDonald (1983) searched clinical records of 1432 psychogeriatric admissions for dementia plus one or more strokes or dementia plus epilepsy and found only 17 patients who might meet the criteria for the diagnosis of arteriosclerotic dementia, a sub-class of multi-infarct dementia.

Warlow (1980) points out that the deterioration in cognitive ability in arteriosclerotic dementia presumed to be caused by a succession of minor vascular catastrophes tends to be "stepwise" but that not all the episodes are "necessarily obvious". That is to say, to account for cerebral-vascular pathology which would not have been predicted from the clinical history, a sub-clinical course of arteriosclerotic dementia must be postulated. We report a clinical search for minor cerebro-vascular episodes which do not amount to strokes in a female chronic psychogeriatric population in a mental hospital.

On a census day, all the psychogeriatric patients in Warlingham Park Hospital (from a total of 227) who had had more than five "turns" of any kind were identified. "Turns" included transient ischaemic attacks, Alvarez' Little Fits, drop attacks, faints, collapses, and tonic or clonic attacks. The patients thus identified were examined for the presence of severe dementia using the Kew Cognitive Map (McDonald, 1969).

Six months later, from the same population, a second group of patients was identified as being on any drug used in cardiovascular disease; this population was presumed to include those patients with diagnosed (and treated) hypertension. Again, the population was examined for the presence of dementia.

The first search revealed 15 patients, none of whom were found to be demented following a stepwise history as judged from a review of the history of the present illness in the case notes. That is to say, no sub-clinical phenomena or pseudo-stroke phenomena were occurring which could have led to a diagnosis of arteriosclerotic dementia being made in any of these cases.

The second search found 26 patients, of whom 7 had a pre-existing psychiatric or neuro-psychiatric condition dating from middle age or earlier (i.e. antedating arteriosclerotic dementia), for example depression, schizophrenia, Korsakoff's psychosis and head injury. Six of the patients in this group were demented, and had presented with an episodic stepwise history.

The high discordance between the pathological findings and the ante-mortem diagnosis of 'arteriosclerotic dementia' is well known. This study has searched for a clinical way of bridging this gap, but has failed to find that in the concept of sub-clinical strokes.

CORRIGENDUM

Journal, May 1987, **150**, 662–673 (R. E. Kendell *et al*). The first line of the summary should read "Computer linkage of an obstetric register and a psychiatric case register made it possible to investigate the temporal relationship between childbirth and psychiatric contact in a population of 470 000 people over a 12-year period: 54 087 births resulted in 120 psychiatric admissions within 90 days of parturition.

A HUNDRED YEARS AGO

Mental disorder caused by jaborandi

Dr Wauzh of Liège, who has great belief in the efficacy of jaborandi as a stimulant of the mammary functions, mentions a case which has recently occurred in his practice, showing that inconveniences may occasionally arise from the administration of this drug. He prescribed ten drops of the fluid extract every four hours for a patient whose milk had ceased for a fortnight, with satisfactory results, the secretion being re-established. After a time, however, the patient began to suffer from extreme nervous excitement, accompanied by a fixed idea that she should murder all her family with a hatchet. On the jaborandi being stopped these alarming symptoms disappeared, and together with them the activity of the mammary glands.

(Jaborandi: The dried leaflets of a Brazilian plant *Pilocarpus pinnatifolus. N.O. Rutaceae*, having diuretic and sudorific properties – *OED*)

Book Reviews

Editor: Sidney Crown

Basic Family Therapy (2nd ed.). By PHILIP BARKER. London: Collins. 1986. Pp 334. £9.95.

Barker aims to provide an easily read introduction to family therapy. This second edition of his book is much more than an update – it is a re-write that tries to create a sense of harmony in this rapidly developing field.

To the uninitiated like myself, family therapists seem both crazy and cavalier. They make bizarre recommendations to families, justifying them as 'paradoxical' and therefore 'strategic'. They complicate the therapeutic relationship by 'live supervision', in which the supervisor watches the session from behind a one-way screen and telephones messages through to the therapist. Scorn is poured on the importance of unconscious communication. Transference and counter-transference are not acknowledged. I therefore started this book with considerable scepticism.

Barker has tried to write a book that is both a work of reference and a practical handbook. His style varies from précis of the main literature to a personal account of his own way of working. He reviews all the major approaches and techniques, trying to give the whole field a sense of unity and cohesion. *En route* he points out key references, thus providing a most useful guide to the literature. His review makes it quite clear that family therapists have a lot to offer us all and are providing accounts of how families develop and how they are structured and function, which are useful even if we don't practice family therapy as such.

Barker's own method of therapy is based on the McMaster model, but in true eclectic fashion he weaves in concepts and techniques from all the other schools. He gives a practical step-by-step account of how to assess, contract, treat, and end therapy with families. He describes in detail both 'systemic' and 'structural' ways of looking at families, and gives many examples of strategic interventions. The account is systematic and reasoned – too much so, perhaps.

He has achieved his objective of providing a "clear, easily read and readily understandable introduction to the subject". This book should certainly be in the library, as it gives a broad picture of the world of family therapy. It is much more than an introduction: it is a textbook, it is a guide to further reading, and it is a practitioners' handbook. Reading it has lessened but not eliminated my scepticism.

C. R. WHYTE, *Consultant Psychotherapist, Humberstone Grange Clinic, Leicester*

Behavioural Psychotherapy: Maudsley Pocket Book of Clinical Management. By I. M. MARKS. Bristol: Wright. 1986. Pp 133. £9.95 pb.

Despite considerable advances in the field of psychotherapy in the last decade, the evidence would suggest that behaviour therapy is still one of the most effective psychological treatments available, albeit for a relatively small number of well-circumscribed disorders. Although descriptions of techniques and guidelines for their administration are well documented in the literature, comparatively little has been written about the clinical management of cases undergoing this form of treatment. Marks has addressed himself to this issue, and the result is a detailed set of instructions regarding screening procedures, interview formats, and letter writing. The style of the book is consistent with the author's orientation within the behaviourist school. Marks is a powerful advocate of the traditional approach which focuses on the achievement of objectively defined targets by direct means rather than the facilitation of internal change through a combination of cognitive and behavioural interventions. The attraction of such an approach lies in its simplicity. Not surprisingly, therefore, this tightly structured volume sets out to reduce the many sources of ambiguity in the psychotherapeutic process by operationally defining every activity the clinician might engage in. Although such an exercise in reductionism can be useful in the treatment of the simple phobias and obsessional disorders illustrated here, clinicians working with more complex cases might find many of these guidelines excessively rigid.

This book has been written primarily for students on nurse therapy training courses and for other professionals working in specialised behaviour therapy units. For the majority of clinicians, however, its main value will be as a source book for diverse questionnaires and rating scales which can be usefully employed to measure response to treatment, be this behavioural or otherwise.

DOUGAL MACKAY, *District Psychologist, Barrow Hospital, Bristol*

Developmental Disorders: The Transitional Space in Mental Breakdown and Creative Integration. By PETER L. GIOVACCHINI. Northvale, NJ: Jason Aronson. 1986. Pp 385. $35.00.

Giovacchini, an American psychoanalyst who has written extensively on character disorders and on adolescence, has now produced an excellent book on the psychoanalytic understanding and treatment of such patients. The book contains three interwoven strands: a discussion of contemporary psychoanalytic concepts, an exposition of the author's theories on character disorder, creativity, and the use of transitional space, and detailed clinical material illustrating the theory.

The general discussion on psychoanalytic concepts is well written, and highlights some of the changes in American psychoanalytic practice over the past few decades. One small criticism is the author's failure to include contemporary Kleinian writers, particularly as, for example, his discussion on transference seems to be informed by the work of Betty Joseph.

The discussion on character disorders is complex, and not always easy to follow. Giovacchini emphasises the importance of Winnicott's notion of transitional space, and the failure of some patients to make creative use thereof. He also stresses the way some severely disturbed patients will try to recreate in the analytic setting the primitive infantile environment which they find most soothing. Herein lie many pitfalls both for the analyst and for the patient.

Giovacchini is at his best in the clinical discussions, which are subtly and sensitively written. He describes some extremely difficult patients and their families, highlighting crucial features of the treatment. He is particularly good in his discussion of the pressures to modify the classical method, and emphasises that such modifications should only be as a planned therapeutic intervention, rather than happening by default.

Overall the book is a well-written account of one practitioner's work with difficult patients, and I can recommend it, especially the clinical discussions, to those who are puzzled by the pressures that such patients place on us.

MARK BERELOWITZ, *Senior Registrar in Child Psychiatry, Maudsley Hospital, London*

Psychotherapy and the Selfless Patient (The Psychotherapy Patient Series). Edited by JEROME A. TRAVERS. New York: The Haworth Press. 1986. Pp 109. $19.95.

This little book from the USA presents a series of papers by psychotherapists of diverse clinical and theoretical backgrounds, including Gestalt, transactional analysis, bioenergetics, client-centred and psychoanalytic. The purpose of the collection is given as "to explore various genres of selflessness" along a spectrum from developmental deficit or failure to developmental ideal. Most of the papers present clinical vignettes or case studies with an accompanying theoretical discussion.

Two case studies are offered demonstrating selflessness as an achievement: "the outcome of a rather mature religious orientation", and "a loss of self that is freely chosen in order to more deeply experience himself and God". For the most part the authors explore selflessness as a developmental deficit, although a view of this as a strategy for survival rather than mere fault is emphasised.

In this, as in other aspects, the self-psychology of Kohut is an important influence and a number of concepts from this approach are introduced. The idea of the self-object, a person experienced by the child as part of the self, who carries out certain personality functions for him and the nature of these functions in the development of self are related to transference phenomena in the psychotherapy. Empathy, vicarious introspection, and use of the therapist's own subjective experience in understanding the patient are recommended.

Other theoretical perspectives include that of attachment theory, discussing the development of self from the base of secure or insecure attachment. Holding and retrieval are described as forms of basic parental attachment behaviour, and it is suggested that their symbolic equivalents could be needed and provided in psychotherapy.

Winnicott and Guntrop are referred to in discussion of the ideas of true and false self and the development of these with a view of the true inner self concealed within a compliant false outer self.

The idea of selflessness as a survival strategy includes examples such as mindlessness and decathexis or 'blanking out'; the threatened selflessness of the suicidal patient and control or mastery gained through this; and the selflessness of the selfless caretaker. Systems theory is mentioned, and there is a sociological view with an analysis of the 1984 United States presidential election.

The book is a light but not unstimulating read. I regret it may be stimulating as much because of its deficits as its good points. The form of eclecticism in the book is such that the clinical and theoretical material is presented relatively undigested, and there is little critical discussion or examination of how one perspective might relate to or influence another. For me there was a kind of flirtation, but failure to follow through. It could serve as an introduction and stimulus to further reading, although the Americain origin and the particular view of varieties of psychotherapy should be borne in mind.

KATE DUFTON, *Senior Registrar in Psychiatry, Claybury Hospital, Essex*

The Analytic Experience: Lectures from the Tavistock. By NEVILLE SYMINGTON. London: Free Association Books. 1986. Pp 347. £22.50 (hb), £8.95 (pb).

If this *Journal* invited reviewers to nominate their Books of the Year, *The Analytic Experience* would head my list. A new book always holds promise of treasures in store, but sometimes the gold is sparse, or the reader has to struggle with turgid prose and impenetrable jargon to discover the buried bounty. Cause for celebration indeed that psychoanalysis is so lovingly and lucidly exposed by Symington in a work that is a joy to read from beginning to end, which clarifies areas shrouded in mystique and confusion that have been alien territory to many who spend their professional life concerned with the minds of men.

For many years Symington was on the staff of the Tavistock Clinic, and his lectures to mental health professionals attending training courses there influenced the development of many young psychiatrists. This book is the result of these lectures, and should ensure that his influence will continue to reach a wide audience, although it must be a cause for regret that he has now emigrated to Sydney. A former Director of the Camden Psychotherapy Unit and a member of the London Institute of Psycho-Analysis, Symington's extensive experience informs his exposition of psychoanalysis as it affects both patient and analyst, and many clinical examples are used to illuminate the nature of the psychoanalytic process. Humanity and humour shine through this book, which amply demonstrates the author's rare gift for communication, rendering the complex simple without ever being simplistic.

The student looking for a basic introduction to Freud's theory and the later developments of psychoanalysis could not do better, but experienced therapists too can benefit from this simple restatement of the familiar and the obvious. Free Association Books deserve an accolade for producing this text, and at the modest paperback price it is a bargain not be missed. A must for the library, for psychotherapy reading lists, and for every clinician who is interested in the function of the mind and the potent therapeutic promise of the doctor/patient relationship.

PAMELA M. ASHURST, *Consultant Psychotherapist, Royal South Hants Hospital, Southampton*

Aspects of the Feminine. By C. G. JUNG. London: Routledge & Kegan Paul. 1986. Pp 179. £3.95 (pb).

Analytical Psychology: Its Theory and Practice. By C. G. JUNG. London: Routledge & Kegan Paul. 1986. Pp 224. £3.95 (pb).

Aspects of the Feminine is a collection of some of Jung's writings about women, female psychology, the image of the female as 'mother' and 'maiden' in the psychology of the male, and the image of the male and other aspects of the masculine in the psychology of the female.

Jung is most interesting and readable when freely exploring his own inner images and his ideas. Although a brilliant clinician and observer of human behaviour, he is not so scintillating when writing about the real external world. His chapter on women in Europe, written in 1927 and uncannily prophetic, is to my mind heavy and boring, although the chapter on 'The love problems of a student', given to a student organisation, runs it a close second.

Jung's theory of archetypes affords a wide and illuminating perspective on history and social movements, and it is this broad and humane view of human psychology and of history which would appeal to the readers of this *Journal.* For example, he saw the loosening of the marriage bond by modern women, and the movement towards spiritual and economic independence, as a result of women's need for true relationships finally free from the remnants of the hampering exclusiveness of mediaeval marriage.

This book includes a useful introduction to archetypal psychology, a full understanding of the 'anima' archetype in man, and a less comprehensive account of the 'animus' archetype in woman (it fell to Jung's wife to attempt the latter).

Analytical Psychology; Its Theory and Practice is a new edition of the five brilliant lectures given by Jung at the Institute of Medical Psychology (now the Tavistock Clinic) in 1935. Respected figures such as Bion, Crichton-Miller, Dicks, Emmanuel Miller, and J. R. Rees attended and made their contributions. Although edited, these lectures and ensuing discussions are basically verbatim transcripts and retain all the humour and mischief of the original events. As a summary of Jung's work and views, at least up to that time, and as a foundation for understanding Jung, they could hardly be surpassed, and anyone seeking an entrance to his work should perhaps start here.

He does not shrink from explaining his divergence from Freud in viewing much of the infantile sexual and incestuous material of dreams and fantasies as essentially symbolic and metaphorical, and his view of neurosis as potentially leading the patient in the right direction. Unfortunately he did not have time in these lectures to explain his concept of the self as a non-ego centre of the personality to which some mature persons need to relate, as perhaps formerly and even now some people relate to the archetypal images of the world's religions. For this the interested reader is directed to the later writings. Jung believed that man's salvation lies within himself, but at the same time found techniques of relating to those 'objectively' experienced impersonal or 'archetypal' images pertaining to the hereditary structure of man which are also known as God or the gods. This belief, that the centre of gravity lies within the individual and is no longer an outside object or person on whom he depends, seems to place Jung alongside the oriental religions in his outlook. But this book is not about religion except insofar as he regards the great religions as psychotherapeutic systems. It is a book by a working psychotherapist who is also deeply concerned with the fundamental nature and structure of the psyche.

J. W. T. REDFEARN, *Director of Training (Adult), Society of Analytical Psychology, London*

Life-Span Research on the Prediction of Psychopathology. Edited by L. Erlenmeyer-Kimling and Nancy E. Miller. Hillsdale, NJ: Lawrence Erlbaum Associates. 1986. Pp 310. £25.50.

This book, dedicated to the late Barbara Dohrenwend, arose from a conference she organised. We are not told when; nor are the eminent contributors introduced to the reader other than by name. The chapters are of two types: research reports, and surprisingly sharp critiques of their methodology. To these latter the researchers have no come-back. The focus is firmly on US psychiatry, with hardly a mention of similar work done elsewhere. (George Brown's studies are referred to, but without a reference.)

This is not an overview of longitudinal studies in psychiatry; nor does the book tackle the methodological issues of such studies in a systematic way. For these reasons, and also because the projects presented range over the whole life span and many, often quite specialised (occasionally even trivial), areas of psychiatry, no-one is likely to read this volume with sustained interest from cover to cover.

I especially enjoyed the chapter on the implications of the prenatal endocrine environment for later gender identity and gender role behaviour; and the long-term follow-up of the Midtown Manhatten study; as well as Lee Robins' and George Vaillant's responses to this and other projects. There were also two interesting chapters on predicting dementia in old age and on Huntington's disease.

This nicely produced book is for the library shelf rather than the individual study.

Sula Wolff, *Honorary Fellow, University of Edinburgh Department of Psychiatry*

Pathology of Eating: Psychology and Treatment. By Sara Gilbert. London: Routledge and Kegan Paul. 1986. Pp 246. £14.95.

Eating and weight are topics which seem to have fascinated researchers as much as the general public over recent years, but most of the many texts which have appeared deal only with one form of problem. By contrast, Gilbert sets out to provide a concise summary of research on the determinants and treatment of anorexia nervosa, bulimia, and obesity. Her book presents a good range of material, objectively described, with extensive and up-to-date references.

The first section is a readable and informative look at the conflicting social and cultural pressures which shape our eating. The second moves on to the pathology of eating, with brief chapters on the medical and biological causes of appetite and weight disturbance but good discussions of psychological approaches. Anorexia and obesity are both given balanced and thorough reviews, each emphasising the danger of an oversimplified view of their aetiology. Binge eating is discussed as an aspect of both of these problems, as well as in a separate chapter. This may reflect clinical fact, but occasionally gives a repetitive feel to the discussion. A fuller account of the problems in classifying eating disorders might therefore have been useful. The third section, on treatment, is most thorough with regard to obesity. The chapters on anorexia and bulimia cover the main therapeutic approaches well, but might have benefited from some additional clinical detail. There is a firm focus on research data, which limits the coverage of some current therapies, with behavioural methods being given greatest prominence.

At times, some indication of the author's working hypotheses would have been welcome to help integrate the evidence presented. Nevertheless, this remains an excellent overview of eating disorders and would be well worth reading, both for psychologists in training or in need of an update on this field and for non-psychologists who may wish to consult selected chapters to broaden their perspective on a particular problem.

Ken Gordon, *Top Grade Psychologist, Winchester Health Authority, Hants*

Depression in the Elderly: Conceptual Issues and Psychotherapeutic Intervention. By Walter S. Weinstein and Prabha Khanna. New York: Philosophical Library. 1986. Pp 193. $12.50.

This book will be of some value in the libraries of those who work clinically with the elderly depressed. However, its use will mainly be as a reference source for more detailed reading; the chapters are too brief to be of greater value either to the novice or the more experienced clinician, being mainly short reviews or summaries of other review articles.

The discussion of conceptual issues is particularly limited. I was concerned at the absence of references to the intrapsychic processes of normal mourning and its distinguishing features from complicated mourning and the morbid depressions. Without these understandings depression cannot be treated by psychotherapeutic methods. I was also disappointed at the omission of descriptions of some of the central intrapsychic developments necessary for a healthy psychological adaption to the latter phase of life, such as a change in attitude to time and death as described by Elliott Jacques in his classic paper on the mid-life crisis.

To those outside the specialty it may come as a surprise that so much has been written about psychotherapeutic interventions in the elderly (there are 25 pages of references at the end of the book). It may be even more of a surprise that the bulk of the outcome literature is optimistic about the worthwhileness of such intervention. Much of the improvement is no doubt due to a reversal of the relative neglect of the elderly by society and the caring professions – indeed, psychotherapy is used in a very broad sense in this book. Those unfamiliar with the differing therapies will not get any idea from the book of the differences in therapist skills required to get a 'reminiscence group' together from those required to conduct psychoanalytic psychotherapy.

In spite of its limitations, this book will do nothing to discourage those interested in working psychologically with the elderly depressed, and hopefully it will lead them to explore the literature further.

BRIAN MARTINDALE, *Consultant Psychiatrist in Psychotherapy, Paddington Centre for Psychotherapy, London*

Theatres of the Mind: Illusion and Truth on the Psychoanalytic Stage. By JOYCE MCDOUGALL. London: Free Association Books. 1986. Pp 301. £25.00 (hb), £9.95 (pb).

Joyce McDougall is one of the most important and creative of contemporary psychoanalytic theoreticians. Being based in France, she is able to draw on some of the French psychoanalytic thinking and render this in a form which is intelligible to her British and American colleagues. She develops here the metaphor of drama and of analysis as a stage in which characters and scenarios from the patient's mind can be enacted. Although dealing with various fundamental kinds of disturbances, it is in the areas of perversion and psychosomatic states where she makes her most original and stimulating contributions.

She refers to perversions as "neosexualities"; her idea is that the person who creates a perversion has reinvented human sexuality, creating a new "primal scene" – one in which all the rules and roles are specified exactly, leaving nothing to chance, and which has the function of keeping intolerable anxiety at bay. The basic anxiety concerns various metaphorical levels of 'castration', involving restriction, humiliation, or even fantasied threats to life itself. In the perverse scenario many kinds of substitutive acts of castration are carried out in a playful way, thus mastering the anxiety through illusion. For example, a perverse man needed to see traces of his partner's faecal matter to bring him to the heights of sexual excitement; as a child his mother had given him frequent enemas and also regularly humiliated him by sending him out in the park with his soiled underpants tied round his head. According to McDougall, these complex sexual creations have an immense hold over the perverse person's life because they function to maintain mental equilibrium and are attempts to deal with profound insults to the sense of self and personal agency and autonomy.

In McDougall's view, psychosomatic patients are also attempting to ward off overwhelming anxiety of a primitive and psychotic nature. She describes how these patients are astonishingly out of touch with feelings and desires. For example, a patient was puzzled by how he could know whether he desired a particular woman or not, although he had "noticed" that he gained an erection in her presence; the erection was as meaningless to him as any other physiological process. McDougall suggests that in their infancy and childhood these patients were not helped to recognise, acknowledge, and understand emotions, which therefore became frightening. These emotions, which were never given access to language, were not recognised as belonging to the self, and nor, at one level, was the body. Threatening emotions were therefore not allowed entry to the conscious mind, but instead were given expression in the body.

Like McDougall's previous book, *Plea for a Measure of Abnormality,* this is rich, evocative, and clinically useful.

PHIL MOLLON, *Regional Psychologist in Psychotherapy (Top Grade), Dryden Road Hospital, Gateshead*

Neighbours: The Work of Philip Abrams. Edited by MARTIN BULMER. Cambridge: Cambridge University Press. 1986. Pp 282. £9.95 (pb).

It is common to view neighbours or neighbourhoods as persons or places living or located nearby. However, they also are part of a process able to enhance the health and well-being of those who live within them. In times when economic changes worsen conditions for many persons, or when austerity policies reduce funds for needed services, neighbours take on particular importance.

Neighbours collects the unpublished work of the late Philip Abrams, the distinguished social scientist who directed pioneering research on neighbours who join families and friends in informal interactions that serve social functions; on neighbouring as a process of everyday relations which sometimes (but not always) appear altruistic and reciprocal in nature; and on neighbourhood care as an organised way to mobilise resources for indigenous social support and mutual responsibility.

This book, edited and integrated with excellent commentaries by Martin Bulmer, includes theoretical and structural perspectives on neighbouring, case studies of streets in various English locations, general propositions, and policy statements from empirically-based research. The overall conclusion is that neighbours can help reduce isolation, promote interaction, and serve psychosocial functions with epidemiological effects in improving health and well-being. The suggestion is that neighbours can have curative and preventive therapeutic possibilities for the elderly, infirm, and other members of society.

The book makes a major contribution to knowledge of neighbours in relation to social dimensions of mental health. It includes an impressive theoretical review which breaks new ground in psychosocial studies, empirical research on neighbouring in different locations, and provocative discussion of policy issues of informal and formal neighbourhood services. It combines qualitative and quantitative methodology, employs microscale social studies and multiunit aggregate analyses, and reports research on the scope and quality of practice.

Bulmer reports that Abrams admired American studies of neighbourhoods, but it is difficult to find more important work on the topic than the research reported here. This book should win an appreciative audience among readers in several social sciences, academic disciplines, and professional fields in addition to those in mental health.

Barry Checkoway, *Associate Professor of Social Work, University of Michigan, Ann Arbor, USA*

Marriage and Family Enrichment. Edited by Wallace Denton. New York: The Haworth Press. 1986. Pp 125. $29.95.

Marriage and Family Enrichment has grown out of the marriage guidance movements. Beginning in Europe and the USA early in the 1960s, a number of counsellors and therapists (including David and Vera Mace in London) sought to develop methods to help couples actively attend to the untapped, underdeveloped strengths in their marital relationships. The aim was to reach people *before* severe problems arise and threaten a breakdown or motivate an approach to a doctor, social worker, or counsellor with a 'sick' marriage.

A gradual accumulation of experience in this preventative, 'well marriage' based approach to relationships has made it possible for Denton and his co-contributors to put together a practical little book. Those who are not familiar with the notion of enrichment will find the book a good introduction to the history, philosophy and practice of this group-based approach. Of particular note are the chapters which systematically explore how leaders can be trained, couples or families selected to participate in the enrichment groups, and timetables ('ground plans') made for the group meetings. The limitations to this approach are also discussed. The chapters are clearly set out, with illustrative case examples.

This book would be of direct interest to those working in community psychiatry, or where professional resources are turned toward prevention and self-help. The enrichment approach could be viewed as a contribution to the growing interest in a holistic/healing approach to couples and families.

Peter Fullerton, *Institute of Marital Studies, London*

Clinical and Pharmacological Studies in Psychiatric Disorders. Edited by Graham D. Burrows, Trevor R. Norman and Lorraine Dennerstein. London: John Libbey. 1986. Pp 394. £26.00.

This book represents selected papers from the 14th CINP Congress, held in Florence in 1984. It is divided into eight sections, covering affective disorders (both pharmacological aspects and clinical studies); anxiety, panic disorders and stress; psycho-neuroendocrinology; schizophrenia; basic neuropharmacology; and Alzheimer's disease and psychogeriatrics. The emphasis is on new developments in biological psychiatry. There are papers on desipramine and central adrenoceptor function, circadian rhythms, biochemical correlates of L-deprenyl, antidepressants, and brain levels of thyroid-releasing hormone. There are a number of other basic neurochemical studies of central and peripheral biogenic amine receptors and theoretical discussions of classification, genetics, and diagnosis. The major emphasis, however, is on new pharmacological therapies. There are reports of new clinical trials of established medications, as well as new drugs, such as alprazolam, fluvoxamine, toloxatane, verapamil, sulpiride, and femotatine.

Almost all the papers are concise and highly technical, reporting a large amount of data. This will appeal to those readers who want to make up their own minds about whether conclusions are warranted from the data presented. Despite their complexity, the papers are well edited and readable. Some of them have extensive introductions reviewing the background for these studies, which readers new to the field will find useful.

Overall this is a well written, well edited and well presented book covering many of the most exciting areas of biological psychiatry. At £26.00 it represents very good value.

Michael A. Reveley, *Senior Lecturer and Consultant in Psychiatry, London Hospital Medical College, London*

Medical Mimics of Psychiatric Disorders. Edited by I. Extein and M. S. Gold. Washington, DC: American Psychiatric Press. 1986. Pp 198. $15.95.

This little book is part of a *Progress in psychiatry* series, each volume of which contains texts based on the papers of a selected American Psychiatric Association conference symposium. Its first two chapters, on "the psychiatrist as physician" and on neurological screening, promote careful physical examination supplemented by the comprehensive battery of investigations more fashionable in the US than here. Physical disorders are seen as diagnostic alternatives to psychiatric disease, and the psychosomatic dimension virtually ignored.

The section on seizure disorders, which takes up almost a third of the book, explores in detail the kindling model as an explanation for the behavioural manifestations of epilepsy and for the efficacy of ECT and anticonvulsants in affective disorder. Briefer chapters on hypothyroidism and on the HPA axis describe clearly, if unexcitingly, the abnormalities of neuroendocrine function found in depression, but with scant discussion of why these associations should occur.

Perhaps most interesting is the editors' contribution exploring the neurotransmitter receptor changes underlying the frequent emergence of depression following alcohol or opiate (particularly methadone) withdrawal. The final chapter, on drug-induced psychiatric disorders, is long on lists and woefully short on mechanisms, or even on critical discussion of the many individual case reports invoked.

This book does not live up to its title's considerable promise, as is perhaps inevitable in a collection of conference papers not conceived for publication as a comprehensive text. It is, however, attractively produced and well referenced, and merits a library browse, although I would not recommend it for individual purchase.

C. L. E. KATONA, *Senior Lecturer in Psychiatry, Middlesex Hospital Medical School, London*

Help Starts Here. The Maladjusted Child in the Ordinary School. By I. KOLVIN, R. F. GARSIDE, A. R. NICOL, A. MACMILLAN, F. WOLSTENHOLME and I. M. LEITCH. Andover: Associated Book Publishers. 1981. Pp 436. £9.95.

This is a recently produced soft-back version of the seminal work of the Newcastle Child Psychiatry Department on the evaluation of psychotherapy in childhood using a community-based sample. The work is already well-known to many child mental health professionals, both academic and clinicians. The advantage of this new edition is its price, which will make it available to many individuals who previously would have felt unable to purchase a single volume for themselves.

The work represents an important landmark in the evaluation of child psychotherapy. The book is well laid out and describes clearly and concisely the method and background to the project, the treatment approaches used, results, and conclusions, and includes a useful and relatively clear technical appendix.

The design of the project was sophisticated, employing multi-method screening and outcome measures and including a control group at risk for psychiatric disorder. The study compared four types of treatment (behaviour modification, nurturing a teacher-aide programme, parent counselling and teacher consultation, and group therapy) applied to children of two age groups: 7–8 and 11–12. Three aspects of the results should persuade researchers and clinicians in child mental health (and perhaps adult mental health as well) to read the book in its entirety. Firstly, treatment is clearly and significantly effective compared with no treatment. Secondly, briefer treatments had the better outcome. Thirdly, the most cost-effective (and therefore the most likely to find realistic application in general child mental health services) were the most efficient in terms of outcome.

A further intriguing issue is the suggestion that the personal qualities of the therapist need to be different in different settings, as indicated by the finding that extraversion and assertiveness were important and had positive correlations with good outcome from treatment, whereas empathy and warmth in therapists did not. The authors infer that in the hurly-burly of school life a greater degree of assertiveness in therapists is required than in the clinic setting, where empathy and warmth may be more necessary.

It could be argued that the study does not adequately reflect the two mainstay psychological treatments that are probably most widely used in child psychiatry clinics: family therapy and individual child psychotherapy. It may thus be difficult to make direct comparisons between this study and clinic-based studies; however, the principles by which this study was carried out and the general issues it raises lay the foundations for the evaluation and design of psychotherapy studies in clinic and community settings.

The book is well laid out and provides something for all types of readership. The research worker will be able to chew over the selection of the treatments, the children, design, methods, and the outcome measures employed to evaluate the change. The clinician will be able to see how the Newcastle team successfully employed well-established psychological treatments in the community and pioneered the way for mental health professionals to work in ordinary schools. The overriding impression is the book is essential reading for child psychiatrists and their colleagues and will become a source reference book for psychotherapy research. Given the continuous vociferous debates concerning the merits of psychotherapy in adults it might be useful if they turn back the covers of this book and consider its contents!

I. M. GOODYER, *Senior Lecturer in Child & Adolescent Psychiatry, University of Manchester*

Anxiety Disorders of Childhood. Edited by RACHEL GITTELMAN. Chichester: John Wiley & Sons. 1986. Pp 271. £20.00.

This book, edited by an eminent American child psychiatrist with a long-standing interest in affective disorders in childhood, focuses specifically on anxiety disorders in the young. It is laid out in twelve clear chapters, two contributed by Gittelman herself; other contributors include other leaders in the speciality such as Werry, Puig-Antich, and Shaffer. All chapters are well-researched, with extensive and up-to-date bibliographies.

The first is an interesting but fairly brief look at anxiety-like disorders in young non-human primates by Stephen Suomi. Next, three chapters are given over to developmental issues, epidemiology, and diagnosis and assessment. A common, almost universal pattern of different specific fears at different ages is traced, but it is emphasised that definitional and measurement problems abound and there are some conspicuously neglected areas, including longitudinal research into the natural history of fears, anxieties, and worries in non-clinical populations, and the impact of family factors on children's fears. No epidemiological data are available specifically regarding anxiety disorders in children, which limits this chapter to a review of the existing (confusing) data on symptom prevalence. Accurate assessment using structured interviews, behavioural, and subjective rating scales is bedevilled by the low reliability among different measures and measurers, and the inadequacy of both the ICD–9 and DSM–III in diagnostic classification is highlighted.

A chapter each is devoted to the association of anxiety disorders with obsessive-compulsive disorder and affective disorder: in the former case little overlap is found; in the latter it is high, but mainly in the sense that a majority of depressed or dysthymic children show anxiety symptoms. There is a lower incidence of affective symptoms in children with primary anxiety disorders. A brief chapter reviews learning theories of anxiety, and a longer one psychodynamic theory. The last three chapters consider treatment, but are restricted to three approaches only: pharmacotherapy, behaviour therapy, and individual psychoanalytic psychotherapy. It will come as no surprise to anyone to learn that drugs have little place. The advice on behaviour therapy is basic, clear, and helpful to a non-psychologist, and similarly that on psychoanalytic psychotherapy to a non-analyst, although couched in general terms rather than focused specifically on treatment anxiety symptoms. One of Gittelman's own contributions is a chapter on correlates and outcome, rather oddly situated in the middle of the book – it might have been more logically placed at the end.

Although clearly set out, easy to read, and a most useful reference source for any aspect of anxiety in childhood, I am not sure that this book succeeds in its aim of defining and clarifying this range of disorders. However, it certainly succeeds in pinpointing aspects in urgent need of further research, including the natural history of fears in non-clinic populations, prospective studies of outcome and, most importantly, the need to tease out separation anxiety from other presentations.

Overall, I would expect most child psychiatrists and many clinical psychologists to find this book helpful.

PATRICIA AINSWORTH, *Lecturer in Child and Adolescent Psychiatry, University of Manchester*

Talking to a Stranger: A Consumer's Guide to Therapy. By LINDSAY KNIGHT. London: Fontana. 1986. Pp 321. £2.95.

This paperback aims to inform the potential psychotherapy patient about the various psychotherapies, to enable them to choose a helpful therapist and the most appropriate therapy. The author is a journalist and mental health film producer, and this book is written from her personal experience of psychotherapy and from numerous discussions with therapists and therapy researchers. The book is well laid out, easy to read, and informative. Each chapter succeeds in conveying the experience and process of the various therapies from the patient's point of view, and provides useful information about mechanisms of change and realistic ideas of the results that can be achieved. There are chapters outlining the nature of psychotherapy, its indications and contra-indications, psychoanalysis, the various schools of dynamic psychotherapy, group therapy, counselling, and sex therapy. The last two chapters indicate how to choose a therapist, and provide a guide on the resources available in the UK. Potential patients may find the chapter on theoretical underpinnings of the various therapies off-putting, however, as it is jargon-ridden and tries to explain too much in too little space.

The main limitation of this book is its scope. Behaviour therapy and cognitive therapy receive mentions only in a brief glossary. Other therapies such as transactional analysis, personal construct therapy and Gestalt therapy receive no mention at all. In addition, the description of therapies suggests that many patients require years of therapy for useful results to be achieved. This is an unnecessarily disheartening message for potential patients, and suggests a lack of awareness of the range of brief focal therapies.

This is a book to recommend to potential patients.

NORMAN D. MACASKILL, *Consultant Psychiatrist with a Special Interest in Psychotherapy, Whiteley Wood Clinic, Sheffield*

Memory and Amnesia: An Introduction. By ALAN J. PARKIN. Oxford: Basil Blackwell. 1987. Pp 227. £22.50 (hb), £7.95 (pb).

This welcome introductory textbook about amnesia is written by a British experimental psychologist who is involved in investigating amnesic conditions. The first four chapters consider current psychological theories about the nature of memory. The remaining seven chapters consider amnesia under the following headings: clinical assessment, the amnesic syndrome, explaining amnesia, ageing and dementia, transient memory disorders, psychogenic disorders of memory, and remediation. The book rounds off with suggestions for further reading, a list of references cited, an author index, and a subject index. The book succeeds in its aim of introducing the contemporary field of work on amnesia. For people unfamiliar with this field, here is a useful entry; for workers in the field, the book is a helpful overview of the field as a whole.

IAN M. L. HUNTER, *Emeritus Professor, University of Keele*

Contents of
THE AMERICAN JOURNAL OF PSYCHIATRY

Volume 144, Number 6 June 1987

Special Articles

703 Psychological and interpersonal issues in space. *Nick Kanas*
710 Childhood cruelty to animals and later aggression against people: a review. *Alan R. Felthous and Stephen R. Kellert*

Regular Articles

718 The Vermont Longitudinal Study of persons with severe mental illness, I: methodology, study sample, and overall status 32 years later. *Courtenay M. Harding, George W. Brooks, Takamaru Ashikaga, John S. Strauss and Alan Breier*
727 The Vermont Longitudinal Study of persons with severe mental illness, II: long-term outcome of subjects who retrospectively met DSM-III criteria for schizophrenia. *Courtenay M. Harding, George W. Brooks, Takamaru Ashikaga, John S. Strauss and Alan Breier*
736 Maternal affective disorders, illness, and stress: risk for children's psychopathology. *Constance Hammen, David Gordon, Dorli Burge, Cheri Adrian, Carol Jaenicke and Donald Hiroto*
742 Changes in AIDS risk behaviors among homosexual male physicians and university students. *Daniel E. Klein, Greer Sullivan, Deane L. Wolcott, John Landsverk, Sheila Namir and Fawzy I. Fawzy*
748 Sexual practices among patients with borderline personality disorder. *George S. Zubenko, Anselm W. George, Paul H. Soloff and Patricia Schulz*
753 Eye versus skin phototherapy of seasonal affective disorder. *Thomas A. Wehr, Robert G. Skwerer, Frederick M. Jacobsen, David A. Sack and Norman E. Rosenthal*
757 Follow-up of pathological gamblers after treatment. *Julian I. Taber, Richard A. McCormick, Angel M. Russo, Bonnie J. Adkins and Luis F. Ramirez*
762 Treatment of a patient with seasonal premenstrual syndrome. *Barbara L. Parry, Norman E. Rosenthal, Lawrence Tamarkin and Thomas A. Wehr*
767 Covariation of criteria sets for avoidant, schizoid, and dependent personality disorders. *Timothy J. Trull, Thomas A. Widiger and Allen Frances*
772 A systematic approach to the delineation of personality disorders. *W. John Livesley*
778 Pharmaco-epidemiology in 136 hospitalized schizophrenic patients. *Julie Magno Zito, Thomas J. Craig, Joseph Wanderling and Carole Siegel*

Editorial

783 Long-term perspectives on persons with chronic mental disorder. *Ronald W. Manderscheid*

Brief Communications

785 Trazodone in the treatment of panic disorder and agoraphobia with panic attacks. *Matig Mavissakalian, James Perel, Kathleen Bowler and Robert Dealy*
788 Reduction of CO_2-induced anxiety in patients with panic attacks after repeated CO_2 exposure. *Marcel A. van den Hout, G. Margo van der Molen, Eric Griez, Harold Lousberg and A. Nansen*
792 Treatment of hyperactive children with D-phenylalanine. *Alan J. Zametkin, Farouk Karoum and Judith L. Rapoport*
795 Clinical characteristics and response to sodium lactate of patients with infrequent panic attacks. *Deborah S. Cowley, Stephen R. Dager, Sue I. Foster and David L. Dunner*
798 Electrocardiographic effects of nortriptyline, phenelzine, and placebo under optimal treatment conditions. *Anastasios Georgotas, Robert McCue, Eitan Friedman and Thomas B. Cooper*
802 Comparison of propranolol, sotalol and betaxolol in the treatment of neuroleptic-induced akathisia. *Bernard Dupuis, Jacques Catteau, Jean-Pierre Dumon, Christiane Libert and Henri Petit*
805 Spontaneous remission of MAOI-induced anorgasmia. *H. George Nurnberg and Philip E. Levine*

Clinical and Research Reports

808 Therapeutic effect of sleep deprivation in patients with premenstrual syndrome. *Barbara L. Parry and Thomas A. Wehr*
811 Dementia in an American–Chinese nursing home population. *Michael Serby, James C.-Y. Chou and Emile H. Franssen*
813 Naltrexone treatment for postconcussional syndrome. *Forest S. Tennant, Jr and Joan Wild*

Contents of The Journal of Nervous and Mental Disease

ISSN 0007-1250

Published by
The Royal College of Psychiatrist

NOTICE TO CONTRIBUTORS

1. *The British Journal of Psychiatry* is published monthly under the auspices of the Royal College of Psychiatrists. The *Journal* publishes original work in all fields of psychiatry. Communications on general editorial matters, including manuscripts for publication, printed matter, and books for review, should be sent to *The Editor, The British Journal of Psychiatry, 17 Belgrave Square, London SW1X 8PG.*

2. Contributions are accepted for publication on the condition that their substance has not been published or submitted for publication elsewhere. The *Journal* does not hold itself responsible for statements made by contributors. Unless so stated, material in the *Journal* does not necessarily reflect the views of the Editor or the Royal College of Psychiatrists.

3. Published articles become the property of the *Journal* and can be published elsewhere, in full or in part, only with the Editor's written permission.

4. Manuscripts accepted for publication are subject to copy-editing, and to editorial changes required for conformity with *Journal* style.

5. We regret that papers unsuitable for publication will not be returned.

6. **General advice to authors** In the assessment of manuscripts submitted to the *Journal*, great importance is attached to clarity and brevity of expression. Authors should read *General Notes on the Preparation of Scientific Papers* (3rd ed. 1974, £0.45, from The Royal Society) and/or Judith Butcher's *Typescripts, Proofs and Indexes* (1980, Cambridge University Press, £2.95). Spelling should follow the *Concise Oxford Dictionary.*

The standard of statistical work in papers submitted for publication has proved to be very variable. Authors using any statistical methods at all are strongly advised to study the paper 'Statistical guidelines for contributors to medical journals' (D. G. Altman *et al, British Medical Journal,* 7 May 1983, **286**, 1489–1493) at the earliest possible stage in preparing their work for publication.

7. **Manuscripts** Two high-quality copies should be submitted and the author should retain a copy. Articles must be typed on one side of the paper only, **double spaced with wide margins,** and all the pages must be numbered sequentially, starting with the title page.

a. The **title** should be brief and to the point. If necessary, a sub-title may be used to amplify the main title. The names of the authors should appear on the title-page, and **their names, degrees, affiliations and full addresses at the end of the paper.**

b. A **summary** should be given at the *beginning* of the article. It should be brief and factual and not normally more than 150 words.

c. **References** should be listed **alphabetically** at the end of the paper, **the titles of journals being given in full.** Authors should follow *Journal* style for the reference list and study the examples given below. Titles of books and journals are printed in italic and should therefore be underlined on the typescript. Reference lists not in *Journal* style will be returned to the author for correction.

Authors should check that the text references and th reference list are in complete agreement as regards dates an spelling of names. The text reference should be in the forr '(Smith, 1971)' or 'Smith (1971) showed that . . . '

DURKHEIM, E. (1897) Le Suicide. Paris. Translate (1952) as Suicide: A Study in Sociology, by J. A Spaulding & C. Simpson. London: Routledge & Kega Paul.

KENDELL, R. E. (1974) The stability of psychiatri diagnoses. British Journal of Psychiatry, **124,** 352–358.

RUTTER, M., TIZARD, J. & WHITMORE, K. (1970 Education, Health and Behaviour. London: Longman.

SCOTT, P. D. (1974) Definition, classification, prognosi and treatment. In Pathology and Treatment of Sexua Deviation (ed. I. Rosen) Oxford: Oxford Universit Press.

'Personal Communications' need written authorisation.

d. **Symbols and abbreviations** Follow *Units, Symbols an Abbreviations: A Guide for Biological and Medical Editor and Authors* (3rd ed. 1977), £2.00, available from th Publications Office of the Royal Society of Medicine. Term or abbreviations which might not be understood by th average reader should be explained at first occurrence.

e. **Tables and Figures** Each table should be on a separat sheet, with an adequate heading; table and heading should b self-explanatory without reference to the text. The desire position of the table relative to the text should be indicated i the left margin.

Figures should be individual glossy photographs, or othe camera-ready prints, *not* photocopies, clearly numbered and captioned below. Avoid cluttering figures with explanator text which is better incorporated succinctly in the caption. A figure intended to occupy a single column should be drawn (or photographed) 80–110 mm wide to allow for a 2/3 reduction; a figure requiring the whole width of the page should be 180–210 mm wide. Lettering (film-set or stencil) should be 12pt sans (initial capital for the first word only) to give 8pt on the printed page. Labels on graphs should read parallel to the axes. Units must be clearly indicated and should be in brackets (*note*—'litre' should be spelled out in full unless modified to ml, dl, etc.).

f. **Photographs** Prints must be taken directly from the original b/w negative (not, for example, from a colour slide or a printed page) and should be glossy and sharply focussed. Labels, arrows, etc. should be shown on a duplicate print or overlay. Do not write anything on photographic prints, and do not use staples or paper-clips on them. These procedures apart, all the comments on figures and tables apply equally to photographs.

8. **Proofs** A proof will be sent to the senior author of an article. Reprints, which are prepared at the same time as the *Journal,* should be ordered when the proof is returned to the Editor.

9. **Letters to the Editor** Letters should not exceed two double-spaced typed pages. They will be edited for clarity and conformity with *Journal* style and may be shortened. There should be no more than five references; tables and figures cannot be used.

Psychiatric
Press, Inc.

Books published by the American Psychiatric Press Inc. are now available throughout the world, except in North America, from Cambridge University Press. These books cover the whole range of subjects of interest to practising psychiatrists and medical practitioners, students of psychiatry and medicine.

ANNUAL REVIEWS

The Annual Reviews of the American Psychiatric Association provide in-depth reviews of selected topics and provide readers with the opportunity to keep up-to-date with fast moving areas in psychiatry.

Psychiatric Update: Volume IV

Edited by **R.G. HALES** and **A.J. FRANCES**

Presents in-depth coverage of: neurotransmitters and neuroreceptors, neuropsychiatry, sleep disorders, eating disorders and the therapeutic alliance and treatment outcome.

700 pp. *0 521 34500 6* **£45.00 net**

Psychiatric Update: Volume 5

Edited by **A.J. FRANCES** and **R.G. HALES**

This volume covers current research in: schizophrenia, drug abuse and drug dependence, personality disorders, adolescent psychiatry, psychiatric contributions to medical care and group psychiatry.

700 pp. *0 521 34499 9* **£45.00 net**

TEXTBOOKS AND MANUALS

Electroconvulsive Therapy: A Programmed Text

M.D. GLENN and **R.D. WEINER**

The book includes discussions of basic concepts of electroconvulsive therapy (ECT) as well as detailed instructions for administering ECT and for monitoring patients.

160 pp. *0 521 34744 0*
Comb-bound £19.50 net

Fundamentals of Psychiatry

R.J. WALDINGER

This lively textbook explains basic psychiatric concepts in simple terms, covering the fundamentals of diagnosis and treatment of mental disorders.

448 pp. *0 521 34484 0* **£25.00 net**

Manual of Clinical Psychopharmacology

A.F. SCHATZBERG and **J.O. COLE**

This manual is a useful practical guide to the selection and prescription of appropriate drug therapies. It is also an invaluable reference work on particular drug therapies, problems and side effects and covers all major standard drugs as well as a variety of less common drugs and drug combinations.

312 pp. *0 521 34711 4*
Comb-bound £20.00 net

Manual of Clinical Child Psychiatry

Edited by **K.S. ROBSON**

Essential information including clinical medicine, psychopharmacology, genetics, education and the law, is combined to form the foundation for a broadly based clinical course in the practice of child psychiatry.

334 pp. *0 521 34712 2*
Comb-bound £27.50 net

Treatment Planning in Psychiatry

Edited by **J.M. LEWIS** and **G.USDEN**

'... should amply reward a careful reading by a psychiatrist or student of psychiatry. It should help the reader to help patients, and that is a worthy accomplishment.'

American Journal of Psychiatry.

435 pp. *0 521 34489 1* **£27.50 net**

University Press

American
Psychiatric
Press, Inc.

Diagnosis and Treatment of Anxiety Disorders

Edited by **R.O. PASNAU**

Distinguished contributors discuss the major anxiety disorders found in adults, ranging from a description of the psychobiology of anxiety and fear, through post-traumatic anxiety, to anxiety and sleep.
272 pp. 0 521 34493 X **£25.00 net**

Lithium Encyclopedia for Clinical Practice

Second Edition
J.W. JEFFERSON *et al*

This new edition updates and expands all the original sections and includes a number of entirely new entries, including bulimia, dosage prediction and dosage measurement, patient and physician guidelines, anaesthesia and surgery, *Herpes simplex* and secondary mania.
340 pp. 0 521 34702 5 Comb-bound
£20.00 net

Psychiatric Aspects of Epilepsy

Edited by **D. BLUMER**

It contains discussions of neurological aspects, medical treatments of epileptic patients, epileptic and pseudoepileptic seizures, major mood disorders and the behavioural effects of temporal lobectomy.
352 pp. 0 521 34492 1 **£25.00 net**

Treatment of Multiple Personality Disorder

Edited by **B.G. BRAUN**

Theories of the aetiology of this recently recognised dis-sociative disorder are presented, the volume combines clinical understanding with up-to-date research into effective therapeutic approaches.
206 pp. 0 521 34701 7
Paperback £12.95 net

BACKGROUND READING

Fundamentals of Research in the Behavioral Sciences

Principles and Practice
F.C. SHONTZ

This book provides a grasp of the broad principles of statistics that are necessary to understand and criticize scientific literature; it gives clear, short numerical examples, all worked out step-by-step.
344 pp. 0 521 34485 9 **£27.50 net**

Psychotherapy Research

Methodological and Efficacy Issues
Edited by **APA COMMISSION ON PSYCHIATRIC THERAPIES**

This grapples with the issues surrounding proof that psychiatry works. It explores such topics as process research, pragmatic and ethical issues, assessment, measuring cost-effectiveness and cost-benefit and statistical issues.
280 pp. 0 521 34746 7 **Pb £12.95 net**

The Psychiatric Therapies

Part I: The Somatic Therapies
Part II: The Psychosocial Therapies
Edited by **APA COMMISSION ON PSYCHIATRIC THERAPIES**

'A major advantage is that one can begin to study the various forms of therapies using only one well written book to get an all-embracing perspective of psychiatric treatments.' *JAMA*
932 pp. 0 521 34496 4 **£50.00 net**

The Affective Disorders

Edited by **J.M. DAVIS** and **J.W. MASS**

This comprehensive review of depressive illnesses includes contributions from leading scientists on their causes, diagnosis and treatment.
'An outstanding synopsis of prevailing thinking and current research.'
Contemporary Psychiatry
448 pp. 0 521 34745 9 **Pb £19.50 net**

Press, Inc.

BACKGROUND READING

Mind and Body

The Psychology of Physical Illness

S.A. GREEN

This discusses the common issues and coping mechanisms that seriously or chronically ill patients invoke in response to their illnesses. Therapeutic techniques to help patients work through their feelings are described.

224 pp. *0 521 34490 5* **£20.00 net**

Borderline Personality Disorder

J.G. GUNDERSON

This guide to the diagnosis and treatment of borderline personality disorder is primarily intended for use by those who have clinical responsibility for the care of borderline patients.

244 pp. *0 521 34494 8* **£19.50 net**

Psychological Trauma

Edited by **B.A. van der KOLK**

The first authoritative reference book to examine the consequences of specific traumas and also the treatment of those whose experiences have overwhelmed both their psychological and biological coping mechanisms.

256 pp. *0 521 34487 5* **£22.50 net**

LEGAL AND SOCIAL ISSUES

Clinical Psychiatry and the Law

R.I. SIMON

This comprehensive volume deals with the confusing legal issues that may confront a psychiatrist in his clinical practice.

592 pp. *0 521 34486 7* **£22.50 net**

The Psychiatric Uses of Seclusion and Restraint

Edited by **K. TARDIFF**

The book includes discussions of the use of seclusion and restraint with different groups of people – children and adolescents, the developmentally disabled and the elderly.

176 pp. *0 521 34491 3* **£20.00 net**

Suicide and Depression Among Adolescents and Young Adults

Edited by **G.L. KLERMAN**

Based on extensive research and experience it identifies the incidence, prevalence and risk factors for suicide and discusses preventive strategies to help young adults and adolescents cope with mental illness.

320 pp. *0 521 34710 6* **Pb £25.00 net**

Terrorism

Interdisciplinary Perspectives

Edited by **B. EICHELMAN, D.A. SOSKIS** and **W.H. REID**

Reports collected from professionals in the fields of psychiatry and law enforcement who have experienced terrorist events report their philosophies about terrorism – why it happens, who it happens to, what social events trigger it off.

202 pp. *0 521 34497 2* **Pb £17.50 net**

Women Physicians in Leadership Roles

Edited by **L.J. DICKSTEIN** and **C.C. NADELSON**

This is a collection of biographies and autobiographies of women physicians, mostly psychiatrists, which forms a fascinating study of women's leadership skills and their development throughout this century.

352 pp. *0 521 34704 1* **Pb £9.95 net**

Cambridge
University Press

American Psychiatric Press Inc.

In the series
CLINICAL INSIGHTS:

PSYCHIATRY AND MEDICINE

Biologic Response Styles

Clinical Implications

Edited by **H. KLAR** and **L.J. SIEVER**

This volume records the area of biologic response styles and the clinical implications. The response styles in monkeys and psychobiological aspects are discussed.

112 pp. *0 521 34714 9* **Pb £9.95 net**

Tardive Dyskinesia and Affective Disorders

Edited by **G. GARDOS** and **D.E. CASEY**

The rationale for this book derives from clinical observations suggesting that neuroleptic-treated patients who suffer from affective disorders may be at increased risk of developing tardive dyskinesia.

128 pp. *0 521 34732 7* **Pb £9.95 net**

Biology of Agoraphobia

Edited by **J.C. BALLENGER**

Clinical psychiatrists and behavioural scientists describe the concept of anxiety and the treatment of agoraphobia and present evidence that panic disorder has a metabolic cause.

128 pp. *0 521 34728 9* **Pb £9.95 net**

Drug Maintenance Strategies in Schizophrenia

Edited by **J.M. KANE**

Intermittent pharmacotherapy and alternative drug treatments are described as well as maintenance regimes for drugs associated with the long-term treatment of schizophrenic patients.

112 pp. *0 521 34739 4* **Pb £9.95 net**

Clinical Care and Information Systems in Psychiatry

Edited by **J.E. MEZZICH**

This discusses the ways in which information systems can be of value to psychiatrists in their work and describes computerised evaluations and applications for mental health treatment.

128 pp. *0 521 34703 3* **Pb £9.95 net**

Treatment of Normal Weight Bulimia

Edited by **W.H. KAY**
and **H.E. GWIRTSMAN**

The eating disorder of bulimia is commonly but inaccurately grouped with *anorexia nervosa*. This volume focuses on understanding and treating the symptom complex as it occurs in bulimic women.

128 pp. *0 521 34720 3* **Pb £9.95 net**

New Developments in Pain Research and Treatment

Edited by **S.J. LEVITAN**
and **H.L. BERKOWITZ**

Psychiatrists, neurologists and pharmacologists describe the endogenous opioid systems in the brain, pain inhibitory systems, pharmacological approaches to pain control and psychiatric factors in the management of pain.

88 pp. *0 521 34736 X* **Pb £9.95 net**

Brain Imaging in Psychiatry

Edited by **J.M. MORIHISA**

The use of positron emission tomography in psychiatry is discussed, as is the importance of knowledge of cerebral blood flow. The mapping of brain electrical activity is described.

CLINICAL INSIGHTS Cont.

PSYCHIATRIC DISORDERS

Personality Disorders

Edited by **J.P. FROSCH**

The purpose of this book is to illustrate current approaches to the theory, diagnosis and treatment of personality disorders from a number of different perspectives.

128 pp. *0 521 34735 1* **Pb £9.95 net**

Substance Abuse and Psychopathology

Edited by **S.M. MIRIN**

The problems of addicts themselves and of their families are discussed, and the psychopathology in families of drug-abusers is described. Opiates, cocaine and alcohol are the main substances treated in depth.

176 pp. *0 521 34733 5* **Pb £9.95 net**

Common Treatment Problems in Depression

Edited by **A.F. SCHATZBERG**

Common problems in the treatment of depression in the hypertensive or cardiac patient, the patient with sleep disorders, the use of antidepressant therapy in organic states and time-limited treatment are all discussed by leading experts.

128 pp. *0 521 34716 5* **Pb £9.95 net**

Post-traumatic Stress Disorder

Psychological and Biological Sequelae

Edited by **B.A. van der KOLK**

Psychological trauma is well-known as a precursor of mental disorder. By clarifying some of the psychological and physiological issues this book contributes to better treatment of people who suffer from its sequelae.

128 pp. *0 521 34740 8* **Pb £9.95 net**

Psychiatric Implications of Acquired Immune Deficiency Syndrome

Edited by **S.E. NICHOLS**
and **D.G. OSTROW**

Covering a vast amount of information the authors have clearly and succinctly described the disease of AIDS as we now know it, in order to replace myth and misunderstanding with information.

160 pp. *0 521 34729 7* **Pb £9.95 net**

New Findings in Obsessive-Compulsive Disorder

Edited by **T.R. INSEL**

The newer forms of treatment are described within the context of modern psychiatric views of the course, nature and diagnostic significance of the phenomena. The book ends with a chapter about the dynamics of the syndrome.

128 pp. *0 521 34727 0* **Pb £9.95 net**

Recent Advances in Post-partum Psychiatric Disorders

Edited by **D.G. INWOOD**

This book comprehensively reviews recent advances in delineating the epidemiology, phenomenology, aetiology and the mother-infant on child morbidity associated with the development of postpartum psychiatric disorders.

THE TAVISTOCK CLINIC

PSYCHODYNAMIC PSYCHOTHERAPY FOR CHILD AND ADOLESCENT PSYCHIATRISTS

This course is being run by the Child and Family Department of the Tavistock Clinic for child and adolescent psychiatrists with an interest in psycho-dynamic psychotherapy who wish to expand and develop their theoretical knowledge and practical skills. It will also provide an opportunity to study relevant psychoanalytical concepts and to link these with ways of working in different clinical settings. The time required will be the equivalent of one half day per week during three ten weeks terms and the course is designed as a series of units which can be built up gradually.

Further details available from: The Training Administrator, The Tavistock Clinic, 120, Belsize Lane, London NW3 5BA. Tel: 01-435 7111 ext 313 or 469.

A general prospectus of training is available on request.

SCHOOL OF HYPNOSIS AND ADVANCED PSYCHOTHERAPY

Since 1980, SHAP has been conducting comprehensive, professional HYPNOSIS/PSYCHOTHERAPY diploma courses based on modern (Ericksonian) methods and NLP.

The courses are in 3 Parts and applications are now being considered for the next Part I Course which spans 5 weekends in Autumn 1987.

For 24-page prospectus and details please send large stamped addressed envelope to Registrar, SHAP, 28 Finsbury Park Road, London N4 2JX.

KUWAIT

University of Kuwait Health Science Centre
Faculty of Medicine

Appointments in Psychiatry

Applications are invited for the following appointments in the Faculty of Medicine:-

a. Associate/Assistant Professor	Psychiatry	1 post
b. Associate Professor	Psychiatry	1 post

REQUIREMENTS FOR APPOINTMENT

Applicants should possess a Ph.D or higher professional qualification, i.e. F.R.C.S., M.R.C.P. etc. in their respective speciality and have conducted and published research in their field. Professor should have 14 years' experience, 4 as an Associate Professor. Associate Professor should have 9 years' experience, 4 as an Assistant Professor.

CONDITIONS OF APPOINTMENT

Salaries: Total monthly salaries will be within the following scales according to qualifications and experience (1 KD = 2.3, US$ 3.5 approximately).

— Associate Professors with clinical appointments	= KD. 989–1149 (8 increments)
— Associate Professors medically qualified with medical science appointments	= KD. 932–1092 (8 increments)
— Associate Professors non-medically qualified	= KD. 875–1035 (8 increments)
— Assistant Professors with clincial appointments	= KD. 768– 928 (8 increments)
— Assistant Professors medically qualified with medical science appointments	= KD. 724– 884 (8 increments)
— Assistant Professors non-medically qualified	= KD. 680– 840 (8 increments)

Social allowance: In addition to the above salary, social allowance is paid in accordance with the rules and regulations of the University.

Clinical supplements: In addition to the above University salaries there will be monthly clinical supplement paid by the Ministry of Public Health for 10 months a year to medical school staff with clinical service commitments. These are:

Associate Professor : KD. 300.
Assistant Professor : KD. 200.

Conference: A member is entitled to attend one academic conference a year which would be subjected to the University rules and regulations.

Gratuity: There is a gratuity of one month basic salary for each year employed payable on termination of contract.

Housing: Suitable furnished, air-conditioned accommodation, electricity and water free of charge.

Medical Care: Free, comprehensive treatment is available in Kuwait under the State Health Service.

Travel: Air tickets are provided from the country of recruitment for the appointee, spouse and upto 3 dependent children under 20 years. Thereafter, return air tickets are issued annually to the country of citizenship or permanent residence. On termination of contract, air tickets are provided to the country of recruitment. A baggage and freight allowance is also provided.

Vacation: 60 days paid annual leave and various national holidays.

Education: This is provided free in State Schools where the instruction is in Arabic. Staff who have to send their children to non-Arabic schools in Kuwait will have the tuition fees of upto a maximum of 3 children met by the University.

Taxation: There is no income tax in Kuwait. Currency is transferable without restriction.

METHOD OF APPLICATION:

Curriculum vitae in duplicate which should include the names of 3 referees, personal particulars, qualifications with dates, career history, teaching experience, research accomplishments and where appropriate clinical experience should be sent to the DIRECTOR OF PLANNING AND ACADEMIC STAFF RECRUITMENT, FACULTY OF MEDICINE, UNIVERSITY OF KUWAIT, HEALTH SCIENCE CENTRE, P.O. BOX NO. 24923 SAFAT, 13110 - SAFAT - KUWAIT, to arrive NO LATER THAN 31ST OCTOBER 1987.

THE CENTRE FOR ANALYTICAL PSYCHOTHERAPY

Applications are invited for the Introductory Course in Analytical Psychotherapy (starting January 1988) — one evening per week, for two terms.

Applicants should preferably be graduates or professionals in health, education or social services; applicants from other professions will be considered. Students who complete this course may apply for the 3-year Clinical Course in Analytical Psychotherapy.

For further details and application form please write to The Chairman of the Training Committee, The Centre for Analytical Psychotherapy, 6 Upper Harley Street, London NW1 4PS. Quoting BJP.

Closing date for applications: 19th Sept. 1987.

Why people cross the country to Cheadle Royal Hospital

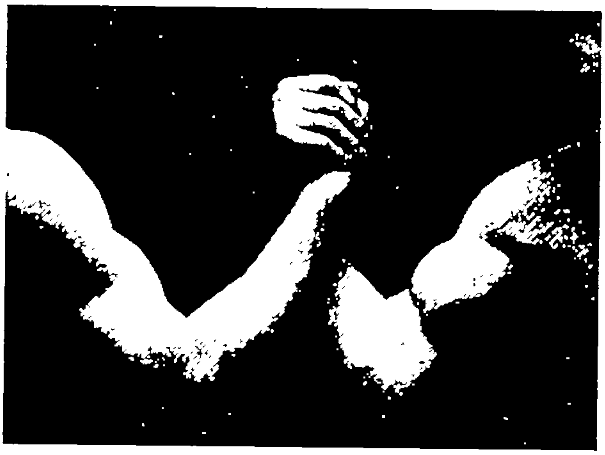
It could be because the hospital offers

- The best in modern treatment methods
- Comfort, privacy and confidentiality second to none
- A long history (more than 200 years) resulting in real respect for traditional values such as loyalty, commitment and service in the care of others
- Total psychiatric care for people ranging from mothers and babies to psychogeriatric patients
- Treatment across the whole range of psychiatric illnesses
- Care for patients' relatives as well as the patient
- A team of staff Consultant Psychiatrists backed by a loyal and dedicated nursing staff
- Specialised and individually arranged treatment programmes for anxiety states, chemical dependence, phobic conditions, eating disorders, alcohol problems, depression, and the whole range of neurosis, psychosis and age-related psychiatric illnesses, all in the Cheadle Royal tradition of respect, dignity and dedication

CHEADLE ROYAL HOSPITAL
Wilmslow Road, Cheadle, Cheshire, SK8 3DG (Tel: 061 428 9511)

Dedicated to mental health

MANY PEOPLE ARE UNDER STRESS. SOME WILL LOSE THEIR GRIP.



Stress is a major causative factor in a wide variety of diseases. It may manifest itself as physical illness or in psychological symptoms. Frequently there is a combination of physical and mental symptoms which may require thorough investigation before the diagnosis is established.

A major facet of treating stress disorders is helping the patient regain control of their own bodies and their own lives.

St. Andrew's Hospital offers a comprehensive treatment programme for all forms of stress disorders. It is conveniently located near the M.1. between London and Birmingham in 100 acres of tranquil parkland near the centre of Northampton.

AUSTRALIA

COMMUNITY SERVICES VICTORIA
OFFICE OF INTELLECTUAL
DISABILITY SERVICES (O.I.D.S.)

CONSULTANT PSYCHIATRIST

A vacancy exists for a Consultant Psychiatrist in the Office of Intellectual Disability Services to provide specialist psychiatric assessment and advice, throughout the State of Victoria, for clients who are intellectually disabled and who need psychiatric assessment and treatment.

QUALIFICATIONS

1. To be a legally qualified medical practitioner registered, or eligible for registration, in the State of Victoria.
2. To be a Fellow of the Royal Australian and New Zealand College of Psychiatrists, or to possess other qualifications recognised as equivalent.
3. Experience in the management of psychiatric disorders in intellectually disabled people is highly desirable.
4. Preference will be given to applicants with experience in post-graduate teaching.

RESPONSIBLE TO: The Director
Client Services Branch
O.I.D.S.

FUNCTIONS:

1. To assist in the development and integration of generic psychiatric services so that they can be used by intellectually disabled persons. This will include liaison with the Office of Psychiatric Services, Health Department of Victoria, and with the Royal Australian and New Zealand College of Psychiatrists, University and major Teaching Hospital Departments of Psychiatry.
2. To provide specialist psychiatric advice to the Director and Assistant Directors, Client Services Branch, concerning individual clients, and advise the Office on broader policy issues.
3. To participate, as required, in education programmes aimed at the providers, and future providers, of generic psychiatric services, to assist them in the treatment and care of intellectually disabled people.
4. To assist, as required, in the training of medical, nursing, professional, and direct care staff, involved in the provision of services to intellectually disabled people.
5. To promote and encourage research into psychiatric disorders in intellectually disabled people.

FOR FURTHER INFORMATION: Dr. John Coldbeck
Senior Medical Advisor
O.I.D.S.
(03) 898 9411

SALARY: Consultant Psychiatrist
Base salary range $A51,174 to $60,147.

CONDITIONS OF EMPLOYMENT:

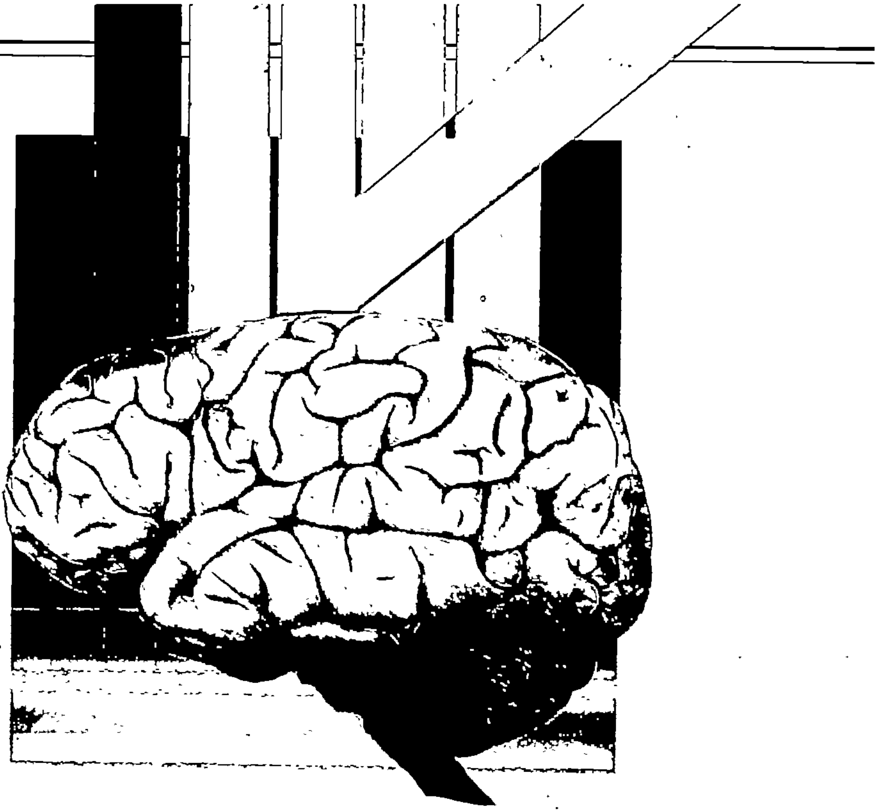
Four weeks annual leave per year is granted, plus public holidays. Long service leave is available after serving a qualifying period. Employer sponsored superannuation may be available.

Applications should include date of birth, address for communication, telephone number, a detailed curriculum vitae including previous employment and experience, together with the names and addresses of three referees.

Applications should be addressed to:
The Recruitment Manager,
Community Services Victoria
6th Floor,
55 Swanston Street,
Melbourne, 3000
Australia.

Closing date for applications is: Friday, 28th August, 1987.

AN EQUAL OPPORTUNITY EMPLOYER



The alternative to tardive dyskinesia?

Effective first line therapy with no reports of tardive dyskinesia when used alone.

Dolmatil is as effective as chlorpromazine,[1] trifluoperazine[2] and haloperidol,[3] but when used alone, in the absence of previous treatment with conventional neuroleptics, it has not been associated with tardive dyskinesia.[4]

The Symptoms of Chronic Schizophrenia
A Re-examination of the Positive-Negative Dichotomy

PETER F. LIDDLE

The relationships between symptoms in 40 schizophrenic patients, selected for persistence of symptoms, were examined. The symptoms segregated into three syndromes: psychomotor poverty (poverty of speech, lack of spontaneous movement and various aspects of blunting of affect); disorganisation (inappropriate affect, poverty of content of speech, and disturbances of the form of thought); and reality distortion (particular types of delusions and hallucinations). Both the psychomotor poverty and disorganisation syndromes were associated with social and occupational impairment; in particular, the psychomotor poverty syndrome was associated with impairment of personal relationships, and the disorganisation syndrome with poor self-care and impersistence at work.

The clinical diversity of schizophrenia has prompted many attempts to define subtypes of the illness. Several recent attempts have been based on the distinction between positive and negative symptoms (Crow, 1980*a,b*; Andreasen & Olsen, 1982; Lewine *et al*, 1983). Negative symptoms reflect deficiency of a mental function which is normally present, for example blunting of affect and poverty of speech. Positive symptoms, such as delusions and hallucinations, reflect aberrant mental activity.

Recent attempts to measure negative symptoms stem from the work of Venables (1957) and Wing (1961). They found that "withdrawal in chronic schizophrenic patients is a unidimensional variable which can be reliably measured. It is defined by such items as: underactivity, slowness, lack of conversation, lack of friends, avoidance of others, poor personal hygeine, carelessness about appearance, and lack of interests" (Venables & Wing, 1962). Electrophysiological evidence that withdrawal was associated with high arousal led Venables and Wing to suggest that withdrawal might be a protective mechanism adopted to cope with a decreased ability to filter sensory input. However, emphasis shifted to the role of social factors in the genesis of negative symptoms, after the demonstration by Wing & Brown (1970) that these symptoms are common in an unstimulating environment, and furthermore are less severe after an "increase in the richness of the social environment" (Wing, 1978).

Subsequently, the evidence that schizophrenic patients with negative symptoms are more likely to have abnormalities such as cerebral ventricular enlargement and intellectual impairment (Huber, 1957; Johnstone *et al*, 1978; Andreasen & Olsen, 1982) has regenerated interest in the role of organic factors. Crow (1980*a*) proposed two types of schizophrenia: type I is characterised by positive symptoms, usually in the setting of an acute illness, while type II is characterised by negative symptoms and indices of cerebral damage, and is usually chronic. Crow did not regard the two types as mutually exclusive, but as independent dimensions reflecting different underlying pathological processes (Crow, 1980*b*).

Andreasen & Olsen (1982) adopted a different view of the relationship between positive and negative symptoms, regarding them as characteristic of two different types of illness. In a sample consisting of consecutive hospital admissions satisfying modified DSM–III criteria for schizophrenia (American Psychiatric Association, 1980), they demonstrated a negative correlation between the occurrence of positive and negative symptoms. They were able to assign about one-third of their cases to each of the positive and negative categories. These two groups of patients differed in many respects, including course of illness, evidence of cerebral ventricular enlargement, and evidence of cognitive impairment.

It is possible that the negative correlation between positive and negative symptoms demonstrated by Andreasen & Olsen (1982) arises from a difficulty in eliciting positive symptoms in the presence of negative symptoms. Another possibility is that the pattern of correlations was influenced by the mixture of acute and chronic cases in their sample. Unless subjects are homogeneous with regard to chronicity, in the sense of having symptoms of comparable persistence over time, there will be a tendency for symptoms to segregate into groups on the basis of their tendency to persist. Although segregation of symptoms on the basis of persistence is of itself important, the question of whether persistent positive symptoms segregate from persistent negative symptoms in a separate issue. It is relevant to the further question of whether symptom type *per se*, rather than the persistence of symptoms, distinguishes between different types of schizophrenia. There are also unresolved issues concerning the assignment of symptoms to the negative symptom group. Andreasen (1982) included inappropriate affect in the negative group, with acknowledged misgivings, whereas Crow (1980*a*) regarded it as a positive symptom. Andreasen also included lack of volition and anhedonia in the group of negative symptoms, and assessed these unobservable attributes of the mental state by rating impairment of self-care, occupational performance, and social function. Since many different attributes of the mental state might in principle contribute to these observable impairments, the validity of this means of assessment remains to be established, and might well be limited to particular samples of patients. Finally, while Andreasen and Crow agree that disorders of the form of thought such as derailment and incoherence are positive symptoms, Lewine *et al* (1983) assign such symptoms to the negative symptom group.

This study attempted to delineate the segregation of symptoms in a sample of schizophrenic patients selected in a manner intended to discriminate in favour of cases with persistent symptoms. No prior assumptions about which symptoms should be regarded as positive or negative were made. The study also included an assessment of cognitive function and of neurological abnormalities, which will be reported separately.

Method

Selection of patients

The following criteria were adopted, with the object of selecting a sample of schizophrenic patients in a manner which discriminated in favour of those with persistent symptoms.

(a) The patient must have satisfied DSM–III criteria for the diagnosis of schizophrenia at some point in the course of the illness, and at the time of interview exhibit at least one symptom from section A or C of those criteria.

(b) The time since onset of illness must be 3–18 years. The lower limit of three years was chosen because Huber *et al* (1975) found that the pattern of illness is generally established by this stage. Cases with an extremely long duration of illness were excluded so as to decrease the likelihood that any observed segregation of symptoms would merely reflect the effects of prolonged illness; a 15-year range of illness duration was the minimum permitting the recruitment of an adequate number of cases from the population available.

(c) The patients must be under regular psychiatric care, but have had no increase in neuroleptic medication or readmission to hospital within the preceeding six months.

(d) Age must be less than 55 years, so as to minimise the influence of the effects of aging on cognitive function.

From all of the patients receiving in-patient, day-patient, or regular out-patient care from one of the seven clinical teams at Warneford Hospital, Oxford, Littlemore Hospital, Oxford, and Fair Mile Hospital, Wallingford, or receiving day or out-patient care at the Eldon Road Day Hospital, Reading, 47 patients satisfying the above criteria were identified. Of these, 7 did not reply or refused to participate in the study. The remaining 40 comprised 12 in-patients, 12 day-patients and 16 out-patients; there were 31 males and 9 females. The mean duration of illness was 10.5 years, and the mean age was 35 years (range 21–54 years).

Assessment of schizophrenic symptoms

Symptoms were rated according to section II of the Comprehensive Assessment of Symptoms and History (CASH) (Andreasen, 1983), and sections 13–20 of the Present State Examination (PSE) (Wing *et al*, 1974). Two separate rating scales were employed because the scope of the definition of each symptom, and the range of symptoms assessed, influence the detectable pattern of correlations between symptoms, and it is therefore valuable to be able to compare the results obtained using different rating scales.

CASH was used because it is designed to provide a comprehensive rating of schizophrenic symptoms. It incorporates the Scale of the Assessment of Negative Symptoms (SANS), which consists of five sub-scales: affective flattening, alogia, lack of volition, anhedonia, and attention impairment. In addition, CASH includes comprehensive ratings of disorders of the form of thought, and of delusions and hallucinations. Most of the items in CASH are rated on a scale of 0–5, reflecting grades of severity.

A number of SANS items demand a detailed knowledge of the patient's lifestyle. Andreasen (1983) recommends that where possible this information be obtained from a third party, such as nursing staff. In this study, with in-patients in the minority, this was not always possible, However, several interviews with each patient were required to allow the administration of the cognitive test battery in a manner that avoided prolonged periods of testing, and these interviews were structured so as to allow a substantial time for informal conversation, including standard questions about the patients' activities and relationships.

The PSE was employed because it has been standardised and because its glossary provides precise definitions of the items to be rated. To avoid prolonged formal examination of the patients, the full PSE was not administered. Questions from sections 13–15 were used to elicit evidence of delusions and hallucinations, and scores were assigned to all syndromes concerned with delusions or hallucinations in the PSE syndrome checklist. Sections 18–20 of the PSE, which involve observations of behaviour, affect, and speech, were also completed.

Data analysis

The symptom ratings were subjected to factor analysis using the program FACTOR from the Statistical Package for the Social Sciences (Nie *et al*, 1975). Initial factors were extracted by the method of principal factors, and subjected to oblique rotation. CASH and PSE ratings were analysed separately.

In the case of CASH rating single items, rather than sub-scale scores, were employed as units of analysis, to avoid having to make any initial assumptions about the relationships between items. Since major disparity in the frequency of occurrence of symptoms necessarily restricts the upper bound of the range of the correlation between items, only those items rated as definitely present in more than 10% of the patient sample were included. One consequence of this limitation was the exclusion of some specific types of delusions and hallucinations, most notably Schneiderian first-rank symptoms, because these items were individually quite rare in this sample.

Since it was not assumed that the items of an individual sub-scale could be taken as measures of the single construct embodied in that sub-scale, a problem arose in the case of the symptoms lack of volition, anhedonia, and attentional impairment. As these symptoms are represented by SANS sub-scales consisting of items measuring self-care, occupation, and social function, which might be regarded as measures of performance in daily life rather than symptoms, the relationship between these items and symptoms was examined separately by determining the Pearson correlation coefficients between these items and symptom factor scores.

In the case of the PSE ratings, the units of analysis representing sections 18–20 consisted of single items. These items record ratings of behaviour, affect, and speech observed at interview. The relatively fine distinctions between individual items in sections 13–15 of the PSE, which record delusions and hallucinations, made it necessary to employ syndrome scores embracing these items as units of analysis. In general, PSE syndromes contain a small number of symptoms which are judged on clinical grounds to be similar. These use of PSE syndrome scores as units of analysis has been justified statistically using data from the US-UK Diagnostic Project and the International Pilot Study of Schizophrenia (Wing *et al*, 1974) which confirmed that PSE symptoms have a satisfactory degree of statistical association with the syndromes to which they have been allocated.

In comparing the results of the factor analysis of the two sets of symptom ratings, it is necessary to bear in mind that the prior existence of statistically justified syndromes in the case of the PSE permits analysis of the relationships between delusions and hallucinations at a different level from that for the CASH ratings. Also, differences in the scope of the definitions of items in different rating scales is inevitable, and is the reason why two rating scales were employed in the first place.

Results

Factor analysis of CASH ratings

The factor analysis of CASH ratings revealed three factors, each having high loadings in a separate group of symptoms (Table I). The first factor loads heavily in poverty of speech, decreased spontaneous movement, and four items which might be regarded as measures of blunting of affect: unchanging facial expression, paucity of expressive gesture, affective non-responsivity and lack of vocal inflection. This group of six symptoms is designated the psychomotor poverty syndrome.

The second factor has heavy loadings in inappropriate affect, poverty of content of speech, and four items which are recognised disturbances of the form of thought: tangentiality, derailment, pressure of speech, and distractibility. This group of six symptoms is designated the disorganisation syndrome.

The third factor has heavy loadings in auditory hallucinations of voices speaking to the patient, delusions of persecution and delusions of reference. This group of symptoms is designated the reality distortion syndrome.

In this sample of patients, the three syndromes are not strongly correlated. There is a weak negative correlation ($r = -0.22$) between the factors associated with the psychomotor poverty syndrome and the disorganisation syndrome, and the other correlations are near zero. The syndromes are thus not mutually exclusive. For example, the probability that a patient has symptoms of the psychomotor poverty syndrome is independent of whether he has symptoms of the reality distortion syndrome.

Factor analysis of PSE ratings

The factor analysis of PSE ratings (Table II) reveals a pattern of segregation of symptoms similar to that obtained for the CASH ratings. The first factor loads heavily in the incongruous affect, poverty of content of speech, incoherence of speech, distractibility, and self-neglect. These symptoms are similar in character to the symptoms of the disorganisation syndrome. The second factor loads heavily in restricted quantity of speech, slowness, and blunted affect, symptoms which are similar in character to those of the psychomotor poverty syndrome.

There is evidence of a sub-division with regard to delusions and hallucinations. A third factor has heavy loadings in the PSE nuclear syndrome (which consists mainly of Schneiderian first rank symptoms) and in sexual and fantastic delusions. This group of symptoms is designated the disintegrative reality distortion syndrome. A fourth factor has substantial loadings in delusions of persecution, delusions of reference, and grandiose delusions; this group is designated the integrative reality distortion syndrome. However, delusions of reference and persecution also have a moderate dependence on the third factor, and hallucinations of voices speaking to the patient depend, albeit weakly, on both factors. Furthermore, the third and fourth factors have a moderate positive correlation ($r = 0.29$) in this sample of patients. There is therefore some justification for considering delusions and hallucinations as a group of related symptoms, irrespective of content.

TABLE I
Factor loadings obtained by factor analysis of CASH symptom ratings

Symptoms	*Factor 1*	*Factor 2*	*Factor 3*
Psychomotor poverty syndrome (high loadings on factor 1)			
Poverty of speech	0.80	−0.01	−0.03
Decreased spontaneous movement	0.95	−0.04	−0.03
Unchanging facial expression	0.85	−0.01	0.05
Paucity of expressive gesture	0.97	0.02	−0.04
Affective non-responsivity	0.82	0.02	−0.00
Lack of vocal inflection	0.90	−0.20	−0.05
Disorganisation syndrome (high loadings on factor 2)			
Inappropriate affect	0.19	0.84	0.09
Poverty of content of speech	−0.08	0.57	0.01
Tangentiality	−0.05	0.94	0.03
Derailment	−0.05	0.94	0.04
Pressure of speech	−0.10	0.61	0.08
Distractibility	−0.00	0.81	0.01
Reality distortion syndrome (high loading on factor 3)			
Voices speak to patient	0.04	−0.07	0.67
Delusions of persecution	−0.19	0.06	0.51
Delusions of reference	0.13	0.04	0.84
Somatic delusions	−0.03	−0.03	0.03

Self-care, occupation and social function

The correlations between the items of the lack of volition, anhedonia and attentional impairment sub-scales of SANS, which are ratings of self-care, occupation and social function, and the factor scores derived from the factor analysis of CASH ratings are shown in Table III. If the factor scores are regarded as measures of the corresponding syndromes, it is apparent that in this sample of patients both the psychomotor poverty and disorganisation syndromes are associated with impairment of self-care, occupation, and social function. However, the syndromes differ in the pattern of their association with these impairments.

The most widespread and severe disturbance is associated with the disorganisation syndrome. In particular, self-care and persistence at work are poor. The psychomotor poverty syndrome is associated with relatively greater impairment of recreational interests and ability to make friendships. There were no significant correlations between factor scores and age, duration of illness, or duration of hospital in-patient care.

Associations between syndromes and medication

The reality distortion syndrome was correlated to current dose of neuroleptic drugs ($r=0.31$, $P<0.10$), current use of anticholinergic drugs ($r=0.53$, $P<0.01$), and current use of benzodiazepines ($r=0.35$, $P<0.05$). The disorganisation syndrome was related to total duration of neuroleptic treatment only ($r=0.31$, $P<0.10$), and the psychomotor poverty syndrome is not associated with any of the variables related to medication.

Discussion

The segregation of symptoms in this sample of patients provides some support for the previously postulated positive-negative dichotomy. Firstly, the symptoms belonging to the Psychomotor Poverty syndrome (blunting of affect, poverty of speech and decreased spontaneous movement) are similar in character to the symptoms that are common to the

TABLE II

Factor loadings derived by factor analysis of PSE ratings

Symptom	*Factor 1*	*Factor 2*	*Factor 3*	*Factor 4*
Disorganisation syndrome (high loading on factor 1)				
Incoherence of speech	0.93	−0.14	0.01	−0.00
Poverty of content of speech	0.68	−0.06	0.20	−0.34
Distractibility	0.74	−0.16	0.03	−0.01

negative symptom groups defined by Wing & Brown (1970), Crow (1980*a,b*), Andreason (1982) and Lewine *et al* (1983). Secondly, in accord with previous studies, this study demonstrates that delusions and hallucinations belong to a group which can be separated from the psychomotor poverty group of symptoms.

The evidence provided by the factor analysis of PSE ratings that there is a division between types of delusions and hallucinations is slender, but gives partial support to the view that first rank symptoms should be distinguished from other types of delusions and hallucinations. Nonetheless, it is important to bear in mind that the factors associated with the disintegrative reality distortion syndrome and the integrative reality distortion syndrome were positively correlated in this sample, suggesting that all hallucinations and delusions constitute a related group of symptoms.

The major difference between the findings of this study and other recent investigations of positive and negative symptoms is the identification of the disorganisation syndrome as a separate syndrome. It consists of symptoms which other investigators have variously assigned to either the positive or negative symptom groups. Disorders of the form of thought constitute a major part of this syndrome. Bleuler (1911) considered it likely that disturbances of association are primary symptoms of schizophrenia, and subsequently many clinicians have accorded them a central place among schizophrenic symptoms. Harrow *et al* (1983) attempted to assess whether disordered form of thought identifies a subgroup of schizophrenic patients with poor outcome. They found that thought disorder persisting after discharge from hospital identified a subgroup with poor outcome, but some patients without thought disorder also had a poor outcome. They concluded that "severe thought disorder is one of several major features of schizophrenia". The present study supports their conclusion.

The relationships between the three syndromes has important implications for predicted relationships between symptoms in different patient samples, and also for hypotheses concerning pathological processes in schizophrenia. In this sample the psychomotor poverty and reality distortion syndromes are not mutually exclusive; some patients have symptoms from both syndromes. This suggests that in a patient sample including a substantial number of cases without any schizophrenic symptoms, correlations between symptoms from these two syndromes would be positive. On the other hand, in a patient sample selected in a manner that favours cases having a single pure syndrome, the correlations between symptoms from the psychomotor poverty and the reality distortion syndromes would be expected to be negative.

For example, the findings of this study predict a negative correlation between the psychomotor poverty syndrome and the reality distortion syndrome in a sample such as that studied by Andreasen & Olsen (1982). Their sample included some acute cases, likely to have reality distortion symptoms only (or perhaps disorganisation symptoms as well), and other cases likely to have psychomotor poverty symptoms only, because DSM-III criteria were modified to accept severe poverty of speech in place of positive symptoms in the mandatory symptoms section.

Furthermore, Pogue-Geile & Harrow (1984) recently studied schizophrenic symptoms recorded 18 months after the patients' discharge from hospital. It is likely that their sample of patients was similar to the patients assessed in this study with regard to persistence of symptoms. In contrast to Andreasen & Olsen, they found a negligible correlation between positive and negative symptoms, consistent with the findings of the current study.

The observation that a patient can have symptoms from more than one syndrome suggests that the syndromes do not represent distinct types of schizophrenia, but instead reflect discrete pathological processes occurring within a single disease. This suggests that there is a fundamental abnormality in schizophrenia, which in any individual case might be associated with one or more of three distinct pathological processes, depending on the patient's constitution and current environment. In principle, the putative pathological processes might be either a cause or a consequence of the fundamental abnormality.

The existence of patients who currently have symptoms of only the psychomotor poverty syndrome, despite selection criteria which demand symptoms from either the reality distortion or disorganisation syndromes at some stage in the illness, demonstrates that the syndromes detectable at any one time can change during the course of the illness. The absence of significant correlation between syndrome scores and duration of illness makes it unlikely that the syndromes follow each other in a specific sequence.

Acknowledgements

This work was carried out while the author was supported by the Wellcome Trust. I am grateful to Dr T. Kolakowska, Professor M. G.

Gelder, Dr D. Clark, Dr T. R. E. Barnes, Dr N. C. Andreasen and Mrs F. E. B. Liddle for suggestions and criticism, to the consultants of the Littlemore, Warneford and Fair Mile Hospitals for permission to study patients under their care, to Mrs A. Slevin for introducing me to patients at Eldon Road Day Hospital, and to the patients themselves.

The Efficacy of Electroconvulsive Therapy in the Treatment of Schizophrenia

A Comparative Study

K. R. ABRAHAM and P. KULHARA

The efficacy of ECT was investigated in a double-blind trial. Twenty-two patients with schizophrenia received trifluoperazine and were randomly allocated to receive eight real or eight simulated ECTs. In the first eight weeks, the group receiving real ECTs showed significantly more improvement as measured on the Brief Psychiatric Rating Scale. However, the groups showed no significant differences from the twelfth week onwards. The superiority of real ECT was not confirmed at the end of six months.

Although electroconvulsive therapy (ECT) is often employed in the treatment of schizophrenia, particularly in combination with neuroleptic drugs, its efficacy has rarely been evaluated by controlled investigations. It is generally believed that ECT is beneficial in ameliorating catatonic symptoms and excitement. However, by itself ECT does not seem to lead to sustained improvement, and relapses frequently occur (Kalinowsky *et al*, 1969). Childers (1964) and Smith *et al* (1967), in two controlled studies, observed that the combination of ECT with antipsychotic medication accelerated the process of recovery in schizophrenics. Kelly & Sargant (1965) and Roth *et al* (1966) showed that when a combination of ECT and drugs was used in the treatment of chronic schizophrenic patients, the improvement was immediate but transitory. In a study of chronic schizophrenic patients, Gambill & Wilson (1966) felt that the ECT–drug combination was only marginally better than placebo.

Many studies on the efficacy of ECT in conjunction with neuroleptic medication have attempted to assess whether the combination is more beneficial than either treatment alone. Ford & Jameson (1955), Kinross-Wright (1955) and Rhode & Sargant (1961) found an ECT-neuroleptic drug combination to be superior to ECT or drug therapy alone. These studies also indicated that patients receiving an ECT-drug combination were discharged earlier from the hospitals. However, Berg *et al* (1959) and Lesse (1959) were unable to demonstrate the superiority of an ECT-neuroleptic drug combination and cautioned that such combined treatment at times had serious side-effects.

May & Tuma (1965) compared five modalities of treatment, in a carefully selected sample of schizophrenic patients, and observed that ECT alone occupied an intermediate position between drugs and psychotherapy alone. May (1968) stated that ECT could not be considered a serious rival to pharmacotherapy or psychotherapy in schizophrenia. In a five-year follow-up study, May *et al* (1976) reported that ECT-treated patients spent shorter periods of time in hospitals after the initial period of treatment in comparison with medicated patients. Rahman (1968), El-Islam *et al* (1970), and Weinstein & Fischer (1971) found ECT in conjunction with drugs to be definitely superior to each treatment alone. In two critical reviews, Turek (1973) and Abrams (1975) commented that most studies were poorly designed, contained heterogeneous groups of patients, and had innumerable treatment modalities and variable lengths of follow-up; they found the data relating to the superiority of ECT-drug combinations unacceptable, and advocated more rigorous research. Salzman (1980) was of the opinion that the literature regarding the therapeutic efficacy of ECT in schizophrenia did not meet contemporary research criteria, and felt that this subject needed more research. Pippard & Ellam (1981), in a report to the Royal College of Psychiatrist, conceded that the status of combined neuroleptic drug-ECT treatment in schizophrenia was far from settled, and identified it as an area for further research.

Since these reviews, Taylor & Fleminger (1980) and Brandon *et al* (1985) have reported much better-designed studies describing the effectiveness of ECT-drug combinations in schizophrenia. Both studies compared ECT-drug combinations with simulated ECT-drug combinations, and showed that those receiving the former improved significantly more in the initial weeks but that this advantage was totally lost with the passage of time.

It appears, therefore, that combined ECT and neuroleptic therapy increases the pace of improvement. The literature also indicates that the more rapid improvement curtails duration of hospitalisation and that subsequent hospital admissions also tend to be of shorter duration.

Notwithstanding the moral and emotional issues involved in the administration of ECT, the possibility that ECT-drug combinations might be cost-effective in terms of duration of hospital stay and maintenance drug therapy offers certain advantages in the management of schizophrenic patients in a country such as India, where resources to cope with a problem of the magnitude of schizophrenia are sparse and under continuous strain. The present study was undertaken to assess the comparative efficacy of an ECT-trifluoperazine combination with a combination of trifluoperazine and simulated ECT. The study was double blind, and had a six-month follow-up period.

Method

Patients attending the out-patient department or admitted to the psychiatric ward were screened for selection purposes. Those satisfying the following criteria were taken up for the study:

(a) fulfilling Research Diagnostic Criteria (Spitzer *et al*, 1978) for a definite diagnosis of schizophrenia
(b) not received ECT before
(c) age at onset of illness less than 40 years
(d) duration of illness not greater than two years.

Using the Present State Examination (Wing *et al*, 1974) one of us interviewed all the patients and randomly allocated them to either ECT or simulated ECT. An informed consent was requested from all patients and their relatives for inclusion in the study. This had two parts: consent for receiving general anaesthesia and muscle relaxants; and information and explanation regarding the purpose and design of the study. It was explained to the patients and their relatives that only half of the patients in the study were likely to receive ECT, although neither the patients nor the other investigator, who evaluated the patients before, during and after the course of treatment, knew to which treatment group a particular patient belonged.

All the patients received a course of eight ECTs or simulated ECTs with intravenous thiopentone sodium (150–300 mg) and scoline (25–30 mg). All the patients were premedicated with atropine. The treatments were administered twice weekly. Trifluoperazine (20 mg/day in divided doses) was given to all the patients, and in the first 16 weeks no change in drug dosage was permitted. In addition, benzhexal hydrochloride, which is an antiparkinsonian agent, and nitrazepam were given as and when necessary. To facilitate drug compliance and follow-up, the drugs were given free of charge to all poor patients.

Using the 18 item version of the Brief Psychiatric Rating Scale (BPRS) (Overall & Gorham, 1962; Overall, 1981) and a clinical global impression scale (CGIS), KRA blindly assessed all the patients before the start of the treatment and at the end of 2,4,6,8,12,16,20, and 26 weeks. The CGIS was based on the clinical impressions of KRA, who rated each patient for the degree of mental illness and for the total improvement since admission, both on a scale of 0–7. The data was analysed by the chi-squared test for non-parametric variables and by the *t*-test for comparison of means. All the *t*-tests were one-tailed. The study commenced on 1 November 1983, and six month follow-up was completed for all cases by 31 December 1984.

Results

The total number of patients at the start of the trial was 28, of which only 22 completed the treatment and six month follow-up; the analysis and results pertain only to these 22 patients. Of the six patients who did not complete the trial, three were in the ECT group and three in the simulated ECT group. One female patient in the simulated ECT group was withdrawn from the study by the clinician in charge because of a deterioration in her condition, and the other five completed the treatment but did not attend regularly for follow-up assessments. Only three patients (one in the simulated ECT and two in the ECT group) were admitted to hospital; the remaining 25 received treatment on an out-patient basis. No patient was given any additional ECT in the study period. For the first 16 weeks drug dosage was held constant. The dose of trifluoperazine was then adjusted according to the needs of the patient, but no patient was given more than 20 mg/day even after 16 weeks. The patients were not given any other medication except nitrazepam and benzhexal hydrochloride.

The two groups did not differ significantly on age, sex, duration of illness, paranoid/non-paranoid diagnosis, or initial BPRS and severity of illness (CGIS) scores. The response to treatment, as indicated by the BPRS scores, is shown in Table I. The ECT group showed more rapid improvement than the simulated ECT group, but by the 12th week the scores for both the groups were similar and did not show any significant difference thereafter till the 26th week.

TABLE I
Inter-group comparison of BPRS scores

Week	*ECT group (n=11)*		*Simulated ECT group (n=11)*			
	Mean	*s.d.*	*Mean*	*s.d.*	t^1	*P*
0	22.36	4.80	22.09	6.07	0.110	NS
2	13.45	6.99	19.55	7.33	1.904	0.05
4	10.54	4.33	17.09	7.79	2.324	0.05
6	8.64	3.11	15.91	8.23	2.613	0.01
8	8.36	4.03	15.0	9.26	2.079	0.05
12	6.64	3.58	12.64	8.32	2.095	0.05
16	6.73	3.66	10.36	7.70	1.346	NS
20	6.36	2.83	9.55	8.97	1.073	NS
26	5.36	3.58	10.36	9.02	1.629	NS

1. One-tailed test.

Mean scores for severity of illness and the degree of improvement as assessed on CGIS for both groups are shown in Figs 1 and 2.

The rate of improvement within the group was examined more closely by comparing the change in scores over successive two week intervals. The ECT group showed continuous improvement at a significant level until the 12th week (Table II). The simulated ECT group also showed significant changes in scores at 0–2 weeks and 2–4 weeks. However, in this group the improvement was not continuous but stepwise.

Discussion

Our study demonstrated that in two groups of patients comparable for age, sex, and duration of illness, the group receiving ECT-trifluoperazine showed significantly greater and more rapid improvement than the simulated ECT group. The drugs given to both the groups were strictly controlled. The group receiving simulated ECT also started to manifest significant improvement from the second week. However, the rate of improvement in the two groups was different. The ECT group displayed continuous improvement until the 12th week; the simulated ECT group showed stepwise improvement over the same period. Despite the faster and more sustained rate of improvement of the ECT group, the two groups did not show any significant difference from the 12th week onwards. At the 26th week the ECT group appears to have fared better. Otherwise, our findings are in agreement with those of Taylor & Fleminger (1980) and Brandon *et al* (1985).

Our study is somewhat limited in measures of outcome. Except for the BPRS we have not employed any other measures, particularly measures to assess depression. However, on the BPRS our patients did not score highly on depressed mood, retardation or hopelessness. Therefore, it could be argued that the improvement found was not specifically linked to improvement in depression, but was associated

with improvements in psychotic symptoms of a schizophrenic nature.

It is commonly accepted that ECT has no role in chronic schizophrenia, and that patients who are young and have been ill for less than a year are likely to benefit most from ECT (Salzman, 1980; Kendell, 1981; Taylor, 1981). The group studied by us was younger than average and had not been ill for more than two years. As such, our patients would have improved without ECT. However, the differential rates of improvement of the two groups lend support to the view that ECT leads to more rapid recovery.

Although our study is comparatively small, in our national context and interest we have demonstrated that ECT is probably cost-effective, as it speeds up the rate of improvement in schizophrenic patients. Because of the small size of the sample it was not possible to study the relationship between response to ECT and clinical symptoms. To further define and delineate the role of ECT in the therapy of schizophrenic patients, more studies involving larger number of patients and longer follow-up periods are needed. Until then, some of the questions pertaining to the efficacy of ECT in the treatment of schizophrenia will remain unanswered.

Expressed Emotion and Schizophrenia in North India

I. Cross-Cultural Transfer of Ratings of Relatives' Expressed Emotion

N. N. WIG, D. K. MENON, H. BEDI, A. GHOSH, L. KUIPERS, J. LEFF, A. KORTEN, R. DAY, N. SARTORIUS, G. ERNBERG and A. JABLENSKY

A bilingual rater was trained in English in a technique of assessing relatives emotional attitudes to patients, and was then required to rate material in Hindi without any further experience. This strategy revealed that the rating of critical comments, hostility and positive remarks could be transferred from English to Hindi without distortion. There were problems with the remaining two scales, over-involvement and warmth, but these were due to technical issues connected with rating and not to cross-cultural distortion.

Measurement of expressed emotion

In order to study the emotional aspects of relationships between psychiatric patients and their relatives, a semi-structured interview, the Camberwell Family Interview (CFI), was developed in the 1960s (Brown & Rutter, 1966; Rutter & Brown, 1966). Originally this was administered to relatives at the time the patient was admitted to hospital.

The interview is tape-recorded, then rated from the recording. Ratings are made on five principal scales: *criticism, hostility, over-involvement, warmth* and *positive remarks. Criticism* is measured by the total number of critical comments made in the course of the interview. A critical comment is carefully defined in a manual used in conjunction with the CFI. *Hostility* is defined as either a generalisation of criticism (1), rejection of the patient as a person (2), or a combination of generalisation and rejection (3). *Over-involvement* can be detected and rated either from the respondent's behaviour during the interview (as with the other scales), or from reported behaviour outside the interview. It comprises several different elements, any one of which can give rise to a high rating. They are: exaggerated emotional responses, unusually self-sacrificing and devoted behaviour, over-protection that is inappropriate considering the patients' age, and an inability to maintain a boundary between the subject's existence and the patient's. Over-involvement is rated on a global scale extending from 0 to 5. *Warmth* refers not to a general quality in the respondent's personality, but to an expressed emotion specifically about the patient. It too is rated on a global scale which runs from 0 to 5. A *positive remark* is a statement which expresses praise, approval or appreciation of the behaviour or personality of the patient. As with criticism, the number of positive remarks made throughout the interview is counted.

On all five scales, raters are required to pay attention not only to the content of relatives comments but also to vocal aspects of their speech, including rate, volume and tone. Despite the niceties of judgement demanded by this latter task, high levels of inter-rater reliability (about 0.8) are normally achieved after attendance at a training course of three to four weeks.

Implications of high EE

The value of this assessment has been established in a series of studies, reviewed by Kuipers (1979). Relatives were characterised as high on expressed emotion (EE) if they scored above certain levels for criticism or over-involvement, or if they expressed any hostility towards the patient. It was found that schizophrenic patients whose illness remitted and who were discharged from hospital to live with high-EE relatives were much more likely to relapse during a nine-month follow-up than those who returned to low-EE relatives (Brown *et al*, 1972; Vaughn & Leff, 1976a). These findings, originally derived from studies of families in London, have been replicated in a study in California (Vaughn *et al*, 1984); and evidence for a causal association between high EE and schizophrenic relapse has been provided by a controlled trial of intervention in high-EE families (Leff *et al*, 1982). In one of the earlier studies the degree of criticism expressed by relatives was also found to predict the outcome of neurotic depression (Vaughn & Leff, 1976a), although the threshold for high and low criticism was much lower than that for schizophrenia. The finding has recently been replicated by Hooley *et al* (1986).

The importance of relatives' EE in psychiatric disorders is now beyond doubt in English-speaking cultures on both sides of the Atlantic. Considerable interest in this measure has also been expressed in other European cultures, and research workers from the Federal Republic of Germany, Holland, Austria and Belgium have been trained in this technique.

The WHO project on outcome of schizophrenia

In 1976 the World Health Organization initiated a multi-centre collaborative research programme on the outcome of schizophrenia, in which the EE measure has been incorporated. The project, on *Determinants of Outcome of Severe Mental Disorder*, is a prospective epidemiological, clinical and social study of schizophrenia and related conditions in different cultures, coordinated by the World Health Organization (Geneva). The study is financed jointly by WHO, NIMH, and twelve field research centres (FRCs) in Aarhus (Denmark), Agra and Chandigarh (India), Cali (Colombia), Dublin (Ireland), Honolulu and Rochester (USA), Ibadan (Nigeria), Moscow (USSR), Nagasaki (Japan), Nottingham (UK) and Prague (Czechoslovakia). All of the FRCs are participating in a 'core' epidemiological and clinical study and sub-groups of centres are carrying out a number of special sub-studies designed to test specific hypotheses about the course of schizophrenia, its social sequelae, and its associations with other diseases.

The 'core' study has set out to identify, over a 24-month period, all the psychotic patients (aged 15–54) making a first-lifetime contact with any 'helping agency' located in or near each of the twelve geographically defined catchment areas in the project. The clinical and diagnostic assessment of these individuals should permit an estimate of the incidence of schizophrenia and related syndromes. The one-year and two-year follow-up assessments of the patients should help to evaluate previous findings of differences in the prognosis of schizophrenia in the developing and developed countries (WHO, 1979).

In addition to the 'core' study, sub-groups of field research centres are undertaking certain special investigations. The one with which this paper is concerned focuses on the effects of patterns of emotional expression and communication in the family on the short-term course of schizophrenic illnesses.

The WHO study of EE and outcome

The centres chosen for a study of EE and outcome of schizophrenia were Aarhus in Denmark and Chandigarh in North India. Danish culture is similar to that in England, both being industrialised Western countries with a well-developed welfare system, whereas India provides a marked contrast. Furthermore, the two-year follow-up of the *International Pilot Study of Schizophrenia* (WHO, 1979) revealed that schizophrenic patients from certain developing countries, including India, had a better prognosis than those from centres in Europe and North America. This raised the possibility that more tolerant family attitudes to illness and handicap might explain or contribute to the better outcome in developing countries. A study of EE in Chandigarh could test this hypothesis.

In training candidates from other European countries to rate EE, we had assumed that the languages and cultures were similar enough for the technique to be transferable from English; but we considered that the cultural and linguistic differences between London and Chandigarh were too great for us to be comfortable with this assumption. The main language spoken in Chandigarh is Hindi, the tonal qualities of which are quite distinct from those of English. Since tone is a crucial element in rating EE, it was obviously essential to devise some method of assessing the transfer of the technique from English to Hindi.

Method

At first sight it may seem that routine tests of inter-rater reliability are sufficient to determine whether the assessment of EE can be transferred from one culture to another. However, a moment's consideration shows that this is not so. Suppose that two bilingual researchers are trained to an acceptable level of reliability in rating EE in English. They then return home and start rating in their native language. They check the reliability of their own ratings in their own language and find it is acceptably high. Unfortunately this does not prove the point. In the process of adapting the interviewing and rating techniques to their own cultural setting, it is inevitable that they will discuss between themselves the difficulties encountered. This could readily lead to a steady drift away from the techniques as taught. Because of their continued dialogue, the two raters could attain a high level of reliability in their own language whenever tested. However, this would by no means guarantee that what they were doing in their own language was the same as they had been taught to do in English. One way to check on this is to train another bilingual subject to rate EE reliably in English and then require him, before he has any experience of rating EE in the second language, to rate tapes of interviews made by the other raters in their native language. Since the 'naive subject', as we shall call him, has had no opportunity to discuss the technique with the other raters, he has no option but to transfer the rating rules that he has learned in English to the second language as best he may. If he then reaches a high level of reliability with the other raters, it demonstrates that what they are doing in their native language must be very close to what was taught in English.

This was the approach we took to test the transfer to the interviewing and rating techniques for EE from English to Hindi. The local researchers (DKM and HB) were trained in English initially, one in London and one in Chandigarh, and achieved acceptable reliability levels on all scales compared with the London centre. The naive bilingual subject chosen was AG, who had no previous acquaintance with the techniques in either language. He was trained in English in the London centre to a satisfactory level of inter-rater reliability on the various scales. He was then required to rate tapes of interviews conducted in the Chandigarh centre in Hindi by the local researchers. It was originally planned that the whole exercise would be carried out on taped interviews sent from Chandigarh. Unfortunately some of the tapes were lost in transit, only six arriving safely in London. These were rated by AG as planned. As it happened, AG decided to visit Chandigarh at this time, and advantage was taken of this opportunity to sit in on four live interviews conducted by the local researchers and to rate them. AG fully understood the necessity to refrain from discussing interviewing or rating techniques with the local researchers until the exercise was completed, and he strictly observed this principle.

Results

Immediately following the training course, AG rated a standard set of tapes used to test reliability. He was found to have reached high levels of reliability on criticism, hostility and over-involvement, but not on warmth and positive remarks. Further attention was given to training AG and in early 1982, just before he visited Chandigarh, AG was asked to rate ten additional English tapes as a final check on his reliability. The product moment correlation coefficients between his ratings and those of the London centre researchers were as follows: critical comments 0.86, hostility 0.90, over-involvement 0.91, warmth 0.20, positive remarks 0.40. As before, his ratings of criticism, hostility and over-involvement were completely satisfactory, whereas those of warmth and positive remarks did not reach even a minimum standard of acceptability. This was not such a drawback as it might seem, since earlier studies had suggested that only the first three scales were associated with the outcome of schizophrenia, and only these three had been used to categorise relatives as high- or low-EE. However, we considered it important to measure these elements of EE in the Chandigarh relatives, since it was feasible that their relationship with outcome might differ considerably from that found in the Anglo-American studies.

The problem AG experienced in becoming reliable on the warmth and positive remarks ratings was unexpected, as trainees are usually able to master all the EE scales by the end of the course. Moreover this problem failed to yield to a further period of training, but because of AG's imminent departure for Chandigarh, we were not able to try other approaches.

The raw scores on the Hindi interviews rated by AG and the two Chandigarh raters (DKM and HB) are displayed in Table I. The data from the six taped interviews which were sent to England have been combined with those from the four interviews at which AG was present. An inspection of this table reveals that the three raters differ little in ratings of critical comments, hostility and positive remarks; whereas for over-involvement and warmth differences are more marked.

For critical comments the intraclass correlation coefficient (ICC) for the three raters is 0.87, a satisfactory value. There are some differences between the raters but these are not consistent and are small compared to differences between the subjects. A positive score for hostility was recorded on only four of the thirty assessments. However, there was complete agreement between the three raters on the presence or absence of hostility in nine of the ten cases. There was considerably more disagreement on emotional over-involvement. The intraclass correlation coefficient (0.21) is not statistically significant. We conclude that the three raters were rating differently, and a visual inspection of the results shows that AG consistently rated higher than either DKM or HB, who differed little from each other. The ICC for warmth is only 0.49, which is barely significant. Once again, AG rated differently from DKM and HB, giving a lower rating on all but one subject. The agreement between the three raters is satisfactory for positive remarks, the ICC being 0.86.

The current criteria for assigning relatives to a high-EE category are: (1) six or more critical comments, or (2) any positive rating on hostility, or (3) a score of three or more on over-involvement. When these criteria are applied to the material in Table I, there is complete agreement between the three raters on the assignment of two relatives to a high-EE category and seven relatives to a low-EE category. In one case (number 7) there is a disagreement, with the two Chandigarh raters scoring the subject low on critical comments while the naive rater scored above the cut-off point for a high-EE rating.

Discussion

It is evident from these results that the rating of critical comments can be transferred satisfactorily from English to Hindi. This is reassuring, since critical comments contribute most to the assessment of EE. In Vaughn & Leff's (1976a) study, 18 out of 21 families (86%) were assigned to a high-EE group on the basis of six or more critical comments.

We cannot be so certain about the transferability of ratings of hostility since so few subjects in the Chandigarh reliability exercise were given a positive rating on this scale. However, the findings suggest that this assessment is also likely to be transferable across the linguistic frontiers without significant distortion.

The position regarding over-involvement is less

satisfactory. AG noted some degree of over-involvement in a higher proportion of subjects than did DKM, and HB was much closer to her Chandigarh colleague in this respect than to AG. Since AG showed no tendency to over-rate on this scale in English, we can conclude that the Chandigarh researchers were likely to be under-rating in Hindi. However, this is not a consequence of cultural differences, as far as we can judge from AG's observation of the live interviews in Chandigarh and discussions with the researchers there.

He reported that judgements of over-involvement were almost exclusively based on overt expression *during the interview* of over-concern or excessive anxiety about the patient's condition. Relatively little attention was paid to reports of behaviour by the subject that reflected over-involved attitudes. This clearly represents a shift of emphasis subsequent to training: during training raters are instructed to give equal weight to the expression of emotional over-involvement and reports of behaviour that suggest it. This drift away from the original convention apparently affected both raters and is likely to have led to under-estimates of over-involvement in the Chandigarh sample of relatives.

The possibility of a drift away from the rating conventions inculcated during a training period has to be guarded against with any rating scale. A number of precautions can be taken. It is very helpful to have a detailed manual of rating instructions available, which trainees can take away with them: this is the case with EE assessment. If there are two trainees in one centre, they should be instructed to carry out inter-rater reliability checks at regular intervals. Finally, trainees should send a proportion of their taped interviews, say one in ten, to the training centre for monitoring by the trainers. This creates extra work for the training centre but is essential for quality control of rating techniques. Of course in the case of Chandigarh it was not possible for the trainers to assess the reliability of ratings of interviews conducted in Hindi. Only the technique of using a 'naive' bilingual rater can reveal the kind of drift that we detected in respect of the over-involvement scale.

Our assessment of the reliability of the transfer of warmth ratings from English to Hindi was clouded by the difficulty AG experienced in mastering this scale in English. He consistently tended to under-rate warmth when assessing English tapes, and the same phenomenon is evident in his Hindi ratings, since both

Chandigarh raters scored higher than he did for the subjects in this study. AG's relatively low reliability with the Chandigarh raters on the warmth scale is almost certainly due to his difficulty with these ratings in both languages. Whether there is an additional problem in transferring this assessment from English to Hindi cannot be determined from these data.

The results for the 'positive remarks' scale are peculiar, since AG attained a reliability on this scale of no more than 0.40 with the English raters, but reached highly satisfactory levels of agreement with the Chandigarh workers in terms of the intra-class correlation coefficient. How is it possible for him to have achieved so close a unanimity with the Chandigarh raters when he appeared to have difficulties with this scale in English? We can only speculate that he grasped the principle behind the rating of positive remarks but was unable to operationalise it satisfactorily in English. However, when he applied it in Hindi without any prior experience of using it in this language he employed it in a very similar way to the other Hindi-speaking raters.

The findings of this study leave us reasonably satisfied that the EE components of critical comments, hostility and positive remarks can be transferred intact from English to Hindi. In the case of over-involvement it was discovered that a drift had occurred away from the rating conventions established during the training. A drift of this kind could just as easily have occurred with researchers rating in English, and does not indicate a specific problem in transferring the rating procedure across languages. However, the presence of this rating bias prevented us from determining whether an additional cross-cultural distortion existed. The difficulties the bilingual rater experienced in achieving reliability on the warmth scale were equally evident in English and Hindi: they therefore represent an idosyncratic problem and not a cross-cultural one.

We conclude that the strategy of using a 'naive' bilingual rater is an effective method of evaluating the cross-cultural transfer of a rating technique. However it is clear that this strategy is viable only if the naive rater is able to become highly reliable on all·the scales to be compared across cultures. This exercise was undertaken to assess the validity of comparing the effects of relatives' EE on the course of schizophrenia in Chandigarh with previous work in English-speaking cultures. We have complete confidence in the ratings of critical comments in Hindi and reasonable confidence in the hostility scores, but some doubts about the ratings of over-involvement. These are the three components which have contributed to the assessment of high-EE relatives in the past. Insofar as critical comments have made the major contribution to the detection of high EE, we consider that a direct comparison between the findings of the Chandigarh study of EE and the work in Britain and North America is meaningful.

II. Distribution of Expressed Emotion Components among Relatives of Schizophrenic Patients in Aarhus and Chandigarh

N. N. WIG, D. K. MENON, H. BEDI, J. LEFF, L. KUIPERS, A. GHOSH, R. DAY, A. KORTEN, G. ERNBERG, N. SARTORIUS and A. JABLENSKY

We measured the components of expressed emotion among two samples of relatives of first-contact patients from Aarhus (Denmark) and Chandigarh (India). The Danes were very similar in most respects to samples of British relatives, whereas the Indian relatives expressed significantly fewer critical comments, fewer positive remarks, and less over-involvement. Within the Chandigarh sample, city-dwellers were significantly more expressive than villagers of all EE components except over-involvement.

As stated in the first paper of this series of three, a study of the relationship between relatives' expressed emotion (EE) and outcome of schizophrenia was undertaken in Aarhus in Denmark and Chandigarh in North India. It was assumed that the techniques of interviewing and rating were readily transferable from English to Danish, these being closely related languages. The same assumption could not be made about English and Hindi, the predominant language in Chandigarh.

The issue was studied by using a bilingual rater. It emerged that the EE components of critical comments, hostility and positive remarks could be transferred reasonably intact from English to Hindi. It was considered likely that over-involvement was under-rated by the Chandigarh researchers, but an adjustment can be made for this bias by lowering the cut-off point for high over-involvement (Wig *et al*, 1986a). These findings allow us to make a direct comparison of the distribution of EE components between samples of relatives from Aarhus, Chandigarh and London.

Method

Research workers in the Danish and Indian centres visited London for training in the interviewing and rating techniques. Satisfactory inter-rater reliability was achieved on all EE scales by the end of the training. In both centres, as part of the standard procedure for trainees, a further set of standard tapes was rated by all researchers after they had returned home, as a check on their rating technique. These proved satisfactory for each individual. In addition, the two London researchers made separate visits to Chandigarh to train an additional researcher and to study the application of the technique under local conditions.

Selection of samples

In the studies conducted in London (Brown *et al*, 1972; Vaughn & Leff, 1976a), patients with a diagnosis of schizophrenia were included on admission to hospital, regardless of length of history. The patients in Aarhus and Chandigarh on the other hand form part of an incidence study co-ordinated by WHO and limited to those making their first contact with psychiatric facilities. In the British samples, however, no differences were found in the distribution of EE components between first-admission patients and the rest, so that it is not unreasonable to compare the Aarhus and Chandigarh samples with the complete British sample.

The Danish and Indian samples comprised all those patients aged 15–54 who contacted a psychiatric service for the first time within a specified two-year period and who could be classified as either schizophrenic or suffering from paranoid or other psychotic states (excluding typical affective psychosis). Each patient was interviewed with the Present State Examination (PSE) and the data obtained were processed with CATEGO program (Wing *et al*, 1974). In addition to a CATEGO class, each patient was assigned a diagnosis by the psychiatrists at the field research centre on the basis of information collected with standardised history and social data schedules in addition to the PSE: we shall refer to this as the patient's 'centre diagnosis'.

Any patient who lived with at least one key relative with whom they maintained daily face-to-face contact was eligible for inclusion in the EE sub-study. Relatives were asked to take part in the Camberwell Family Interview (CFI) (Brown & Rutter, 1966; Vaughn & Leff, 1976b).

The great majority of British patients not living on their own were either in parental or marital households. In the latter case the spouse was interviewed; in the former, both parents were interviewed if available. In Chandigarh many patients (37%) lived in extended families, which gave the researchers a choice of relatives to interview. They were guided in their choice by considering who spent most time with the patient, as determined from a preliminary discussion with the patient. In a number of families the patient's mother-in-law, sister-in-law, or son-in-law was interviewed, in addition to a parent or spouse. In Aarhus, as in London, the spouse was the interviewee in marital households; but in parental households only one parent was interviewed, due the pressure of other research work. In the majority of instances (75%) the mother was chosen as the respondent. In the earlier British Studies the convention was adopted that where two relatives in one household were assessed for EE, the higher rating on each index was used to categorise the family as high or low in EE. The absence of data from a second parent in the Aarhus group means that this sample is likely to under-represent the higher levels of EE and is not entirely comparable with the other two samples. Nevertheless, comparison is worthwhile as long as this reservation is kept in mind.

Results

Danish sample

In Aarhus, 28 patients included in the EE study were given a centre diagnosis of schizophrenia; of these 25 were assigned to CATEGO class SOP, which corresponds to a diagnosis of schizophrenia (SOP encompasses classes S+, S?, P+, P? and O+), one was assigned to class O?, and the other two were classified as D+, equivalent to depressive psychosis. Both the depressed patients were diagnosed by the centre psychiatrists as depressive psychotic at the two-year follow-up. Nevertheless, for the purposes of comparability with the Chandigarh data they have been retained in the initial Aarhus sample. Thus EE data are available for 28 Aarhus relatives.

Indian sample

Of the 78 patients in Chandigarh given a centre diagnosis of schizophrenia, 50 also received a CATEGO class of schizophrenia. Of these, 31 were assigned to class S+, indicating that they exhibited at least one Schneiderian first rank symptom. The CATEGO class does not take account of the history, which is of considerable importance in those patients who present with an acute psychotic disturbance which settles very rapidly, often before a full PSE can be carried out. Furthermore, the distribution of EE components was found not to differ between relatives of centre-diagnosed schizophrenics with and without a CATEGO classification of SOP. For these reasons, all 78 patients with a centre diagnosis of schizophrenia have been included in this analysis. 104 of the relatives with whom these patients lived were rated for EE, 67 being parents, 29 spouses and 8 other kin.

Patients in the Indian sample were drawn from two different environments; the city of Chandigarh, which is a

TABLE I

Distribution of EE components among relatives from London, Aarhus and Chandigarh

	London	*Aarhus*	*Chandigarh*
Mean number of *critical comments*	8.4[1]	4.5	1.9
Proportion of relatives showing *hostility*	18%[1]	21%	16%
Proportion of parents showing *over-involvement*	36%[1]	n.a.[3]	4%
Mean score on *warmth*	2.3[1]	2.5	2.0
Mean number of *positive remarks*	2.6[2]	3.1	0.8
Proportion of relatives classed as *high-EE*	54%[1]	54%	23%
Proportion of hostile relatives with low criticism	0%	0%	29%
Correlation between warmth and critical comments	−0.44	−0.57	0.10
Number of patients assessed	37	28	78
Number of relatives assessed	46	28	104

modern urban centre designed by the Swiss architect Le Corbusier, and a rural area of villages in Ambala district. The city dwellers include a high proportion of the professional classes, whereas the villagers are mostly peasant farmers. A more traditional way of life is maintained in the villages, an index of this being the proportion of patients living in extended families—20% of urban dwellers compared with 75% of villagers ($P<0.001$). (Comparisons were tested for significance by the t statistic, χ^2 or Fisher's exact test where appropriate.)

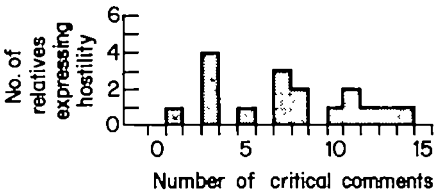

FIG. 2 The relationship between expressed hostility and critical comments among relatives of schizophrenic patients in Chandigarh.

Distributions of EE components

The data on EE components are set out in summary form in Table I.

Critical Comments

The distribution of critical comments among Aarhus and Chandigarh relatives is shown in Figure 1 with comparable data for British relatives, from the study of Vaughn and Leff (1976a). It can be seen that 56% of Chandigarh relatives made no critical comments at all, compared with 29% of Aarhus relatives and 28% of British relatives ($P<0.001$). Furthermore, while 16% of British relatives scored 15 or more, no Chandigarh relative made more than 14 critical remarks. Only two of the 28 Aarhus relatives scored more than 15 on criticism, but the sample was small and the omission of a second parent introduces a bias against more extreme responses. Nevertheless, the shape of the Aarhus distribution of critical comments closely resembles that for British relatives and the proportion rated high on this component is very similar (36% compared with 43%).

It is clear that Chandigarh relatives are far less expressive of criticism than British or Danish relatives, but there are also interesting differences *within* the Indian sample. The mean number of critical comments made by urban relatives was 2.42, compared with only 0.58 for rural relatives ($P<0.01$). These means contrast sharply with the figure of 8.4 for the British sample (Vaughn & Leff, 1976a).

The mean criticism score for the Danish patients was 4.5, intermediate between the Indian and British means. This figure may have been artificially depressed by the absence of respondents who were extreme on this measure or it may indicate a genuine cultural difference, the Danes being less inhibited in expressing criticism than the North Indians, but not as expressive as the Londoners.

Hostility

In previous British and American studies of EE, hostility was a relatively uncommon attitude which almost always occurred in conjunction with excessive criticism. In our Chandigarh sample hostility was expressed by 16% of relatives. Of the 17 hostile relatives, 16 were city-dwellers with only one from the rural area; a significant difference ($P<0.01$). The proportion of Chandigarh relatives voicing hostility (16%) compares with 21% for Danish relatives and 18% for British relatives.

All the hostile Danish relatives scored above the threshold of six critical comments for high criticism, whereas 29% of Chandigarh relatives making hostile remarks scored below this level of criticism. However, when the distribution of critical comments in hostile relatives was examined, it was found that only one relative made fewer than three critical remarks: in Figure 2 hostility can be seen to cluster at three critical comments, which is the modal value. This shows that hostility occurs at much lower levels of criticism in Chandigarh relatives than in Danish or British relatives, which could be taken to indicate that the threshold for high criticism should be set lower for Chandigarh relatives, possibly at three critical comments instead of six.

Warmth

The Chandigarh relatives were found to have similar scores for warmth to the Europeans, the average rating being 2.04 compared with 2.54 for the Danes and 2.32 for relatives from Vaughn & Leff's study. As with critical comments, however, there was an interesting difference between urban and rural samples. The mean level of warmth for urban relatives was 2.34, compared with 1.23 for rural relatives ($P<0.001$).

Relationship between warmth and critical comments

In sorting through the data it became apparent that a surprising number of Chandigarh relatives were high on both critical comments *and* warmth, a combination that was not commonly encountered among Anglo-American families. In order to check this impression, the correlation coefficient between the scores on warmth and critical comments was calculated for the English, Danish and Chandigarh samples. Three English samples were subjected to this analysis: the relatives from the naturalistic study of schizophrenia by Vaughn & Leff (1976a); the relatives from the intervention study in families of schizophrenics by Leff *et al*, 1982); and a group of parents of patients with anorexia nervosa (Szmukler, personal communication). The correlation coefficients for the English groups were −0.44, −0.45, and −0.46 respectively, and the figure for the Danish data was −0.57: these correlations are all significant ($P<0.01$) and are remarkably consistent across studies and diagnostic groups. By contrast, the equivalent correlation coefficient for the Chandigarh relatives was 0.10, which is significantly different from the figures for the English and Danish relatives (critical ratio = 2.86, $P<0.01$).

These findings indicate that warmth and criticism bear a different relationship to each other among British and

Danish relatives than among Chandigarh relatives. In the Indian sample warmth is as likely to be associated with high criticism as with low criticism, whereas in the English and Danish samples warmth is much more likely to accompany low criticism.

Over-involvement

In the Anglo-American studies, over-involvement was found much more commonly in parents than in spouses, and significantly more often in mothers than in fathers. In the recent British studies, a score of 3 or above is taken to indicate high over-involvement: this level was reached by 36% of Vaughn & Leff's parents of schizophrenics. Of the 67 parents in the Chandigarh sample, none scored more than 3 on this scale, and only three parents (4%) scored 3. This is of course a highly significant difference from the comparable figure for the English parents ($P<0.001$).

None of the 29 spouses originally interviewed scored above 2 on over-involvement, but one patient left the parental home during the course of the one-year follow-up and went to live with her husband, who scored 3 on over-involvement. Thus only 1 out of 30 spouses was rated as high on over-involvement.

As we have seen in Paper I, it is likely that the Chandigarh raters were underestimating the degree of over-involvement present in the patients' families. However, even if a score of 2 rather than 3 is taken to indicate over-involvement, only an additional seven relatives, all parents, would be included. This would bring the total of over-involved parents to 15%, which is still significantly lower ($P<0.05$) than the comparable proportion among English parents. So even when some adjustment for the possible under-rating of this component is made, Chandigarh relatives are significantly less expressive of over-involvement than English relatives.

There is a problem in making comparisons with the Danish material, since only one parent was interviewed in each household, and mothers were over-represented. Of the nine mothers assessed, five (56%) scored 3 or more on over-involvement, which compares with the British figure of 44%. It is noteworthy than no Danish mother scored high on both over-involvement *and* criticism, whereas this combination occurred in 25% of British mothers.

Positive remarks

In a recent English series (Leff *et al*, 1982) the average number of positive remarks made by relatives of schizophrenic patients was 2.55, while for our Danish relatives the mean was 3.14. In the total Chandigarh sample the comparable figure was 0.79, significantly lower ($P<0.001$). Once again, dividing the Chandigarh relatives into urban and rural dwellers produced an interesting difference, the mean for urban relatives being 0.96 and for villagers 0.39 ($P<0.02$).

The EE index

In current British research, families are assigned to the high-EE category if they score 6 or more on critical comments, *or* show any degree of hostility, *or* are rated at 3 or above on over-involvement. The proportion of relatives in our samples rated as high-EE is shown in Table I. The proportions in the London and Aarhus samples are identical (54%), while only 23% of Chandigarh relatives were classed as high-EE. Within the Chandigarh sample, 30% of urban families and only 8% of rural families qualified as high-EE.

Discussion

On virtually every characteristic of EE the Danish relatives were very similar to British relatives both in terms of mean score and in the inter-relationship of the components. Hostility occurred only in the presence of high criticism, and warmth was significantly and inversely related to criticism. The absence of high criticism among over-involved Danish mothers is a notable difference from the British group, but cannot be given much weight in view of the small size of the sample. The same reservation applies to the relatively low mean score for critical comments: the accumulation of a larger and more representative sample is essential before concluding that Danish relatives of schizophrenic patients are less critical than their English counterparts. Despite the lower mean criticism score, the proportion of Danish relatives rated as high on EE, 54%, is identical to that in Vaughn & Leff's sample. This is because of the lack of overlap between high criticism and over-involvement among the Danes, so that every over-involved Danish relative increased the number in the high-EE group. As a consequence, one would anticipate a relapse rate among the Aarhus first-admission sample comparable with that in London. Unfortunately, the small size of the initial Aarhus sample for the EE study was further reduced: some patients' initial illness failed to improve during the 12 months following the initial examiniation, and others did not return home but were placed in sheltered accommodation. The attrition of the sample made it impractical to analyse the relationship between EE and outcome for the Aarhus cases.

The relatives of the Chandigarh schizophrenic patients were found to be significantly less expressive of critical comments, over-involvement and positive remarks than Danish or English relatives. However, the degree of warmth and of hostility expressed did not differ signifcantly between the cultural groups. The differential effect of culture on the various components of EE is puzzling and needs further exploration. It must be emphasised that these ratings were made from an interview with the relative, and a basic assumption of the technique is that the relative's responses to questions about the patient reflect current behaviour between the individuals. To the extent that the relative's EE has been consistenly found to be related to the outcome of the patient's psychiatric condition, this assumption appears to be justified. More direct evidence has also been provided by recent parallel studies of relatives' EE and observations of interaction between relatives and patients (Miklowitz *et al*, 1984). This work was conducted with American subjects and is now being replicated with a British sample. Unfortunately the cultural distance between North American, European, and North Indian relatives is so wide that it cannot be assumed that the same relationship will hold in Chandigarh between responses to an interviewer and current behaviour. The follow-up of the patients' clinical state will throw some light on this issue, but observations do need to be made of direct interaction between relatives and patients in India.

Within the Chandigarh sample, rural relatives were rated significantly lower than urban relatives on critical comments, hostility, warmth and positive remarks. In fact over-involvement was the only EE component for which this effect could not be demonstrated, but this may well be a consequence of the rarity of this attitude in Chandigarh, where it was rated in only four individuals. Of the urban families, 30% were classified as high-EE, compared with only 8% of rural families ($P<0.01$).

A number of possible explanations can be put forward for this urban/rural difference in the expression of emotion. It is almost certainly bound up with differences in life-style, any of which might be responsible. For instance, the rural dwellers were much more likely to live in extended families than the city-dwellers, whose households were more often nuclear. It is conceivable that the emotions generated by family relationships become dispersed throughout the network of an extended family, instead of being concentrated in the much smaller group of a nuclear family. This hypothesis was tested by examining the distribution of high-EE families between nuclear and extended households: in fact 21% of nuclear families and 25% of extended families were classified as high-EE, a non-significant difference. Another possible explanation is based on evidence that in many non-Western cultures emotional distress tends to be more readlily expressed in somatic rather than psychological terms (Leff, 1981). However, this would be expected to occur predominantly with the negative emotions, such as criticism and hostility, but in this study the positive emotions of warmth and positive remarks were equally affected. It has also been argued that the expectations of rural relatives are lower and their tolerance higher than those of urban relatives (Waxler, 1979). Once again, though, this would explain the muted expression of negative emotions by the villagers but not of positive emotions. Finally, it has been postulated that the increased emphasis on the individual in Western culture has led to a greater value being placed on introspection and on the untrammelled expression of emotion (Leff, 1981). This influence would affect the whole range of positive and negative emotions. However, the data required to test this hypothesis were not collected in this study.

Before considering the implications of these results for the course of schizophrenia in Chandigarh, we need to discuss an unexpected and surprising finding from this study. Whereas critical comments and warmth were significantly negatively correlated among the Aarhus relatives and in several British studies, their correlation for Chandigarh relatives was positive, although very small and non-significant. This indicates that Chandigarh relatives commonly express high criticism and high warmth at the same time, whereas this combination is rare among British relatives. A European might well regard warmth and criticism as incompatible emotions, whereas North Indians appear to have no difficulty in expressing both about the same patient during the hour of the interview. It may be that this is another example of a broad difference between developing and developed countries, whereby concepts that are considered mutually exclusive in one area are able to co-exist harmoniously in another. Whatever the explanation, the combination of high warmth and high criticism expressed by some Chandigarh relatives has potentially important implications for the patients concerned, since warmth was found to be protective in the British studies (Brown *et al*, 1972; Vaughn & Leff, 1976a), whereas criticism had the opposite effect. When the follow-up data are analysed, we shall explore the possibility that high warmth may neutralise the deleterious effect of high criticism.

As discussed above, it is not possible at this stage to decide whether the lower levels of EE rated in Chandigarh relatives compared with Danish and British relatives actually reflect a lower emotional tone in interactions with patients. If they do, then this should be detectable in terms of a lower relapse rate in this sample of Chandigarh schizophrenic patients than in comparable groups of British patients. Furthermore, the striking urban-rural differences in EE exhibited by the Chandigarh relatives should also be reflected in differential relapse rates for the patients. The test of these hypotheses lies in the one-year follow-up data, which are presented in the third paper of this series.

III. Influence of Relatives' Expressed Emotion on the Course of Schizophrenia in Chandigarh

J. LEFF, N. N. WIG, A. GHOSH, H. BEDI, D. K. MENON, L. KUIPERS, A. KORTEN, G. ERNBERG, R. DAY, N. SARTORIUS and A. JABLENSKY

We conducted a one-year follow-up of patients who had made a first contact with psychiatric services in Chandigarh, North India, and had been assigned a diagnosis of schizophrenia. The expressed emotion (EE) of the patients' relatives was assessed early on. We found the same associations between the individual components of EE and relapse of schizophrenia as in previous Anglo-American studies, but only the association between hostility and relapse was statistically significant. Applying the same criteria as in the Anglo-American studies for 'high EE', we found a significant relationship between high EE and relapse. This relationship was not explained by other factors often associated with higher relapse rates. We conclude that the significantly better outcome of Chandigarh first-contact patients compared with a London sample is largely due to the significantly lower proportion of high-EE relatives in the North Indian sample.

The two-year follow-up of the *International Pilot Study of Schizophrenia* (WHO, 1979) revealed that the outcome for schizophrenic patients in the centres at Agra and Ibadan was substantially better than in the centres situated in Europe and North America. This could not be attributed to divergent diagnostic practices, since there was close agreement on the diagnosis of schizophrenia between psychiatrists at the Indian and Nigerian centres and those in the developed centres. Another possible explanation was that the better outcome in developing countries might be attributable to more tolerant family attitudes to illness and handicap. An opportunity to test this hypothesis was presented by the initiation of the WHO *Determinants of Outcome* project. The design of the 'core' study of first-lifetime contact, and of the sub-study of the relationship between relatives' expressed emotion (EE) and outcome of first-contact schizophrenia, have already been described in the two preceding papers (Wig *et al*, 1986a; Wig *et al*, 1986b). In this paper, we present data on the relationship between relatives' EE and outcome in Chandigarh.

Before investigating possible links between relatives' EE and relapse of schizophrenia in India, it was essential to determine whether the techniques of assessing EE could be transferred intact across linguistic and cultural frontiers. A preliminary study was conducted using a 'naive' rater who was bilingual in English and Hindi. He was trained to rate EE in English and then without further experience was required to rate interviews conducted in Hindi by the Chandigarh interviewers. The results of this study (Wig *et al*, 1986a) indicated that two major components of the EE index, critical comments and hostility, could be transferred from English to Hindi with little or no distortion. In the case of the third major component, over-involvement, it appeared that the Hindi-speaking raters were under-estimating the scores on this scale. However, an adjustment can be made to compensate for this possible source of bias by lowering the cut-off point for 'high over-involvement'.

Method

All 207 patients entering the 'core' component of the *Determinants of Outcome* study in Chandigarh were considered for the study of relatives' EE. Patients were drawn from two different environments, the city of Chandigarh and an adjacent block of rural villages in the Ambala district. A high proportion (66%) of the city dwellers are literate compared with 20% of the villagers, most of whom are peasant farmers. A traditional Indian way of life characterises the villages: 75% of patients came from households occupied by extended families, while in the city the corresponding proportion was only 20% ($P<0.001$).

Patients included in the 'core' study had to be living with at least one key relative with whom they maintained daily face-to-face contact to be eligible for inclusion in the EE sub-study: there were 103 such patients. Relatives were asked to take part in the Camberwell Family Interview (CFI) (Brown & Rutter, 1966; Vaughn & Leff, 1976b). The relatives of 15 patients eligible for inclusion in the EE sub-study refused to be interviewed, all but one of these being city-dwellers. Interviews were finally collected for 93 patients, 78 of whom had a centre diagnosis of schizophrenia.

The interview procedure in the city closely resembled that in the developed centres, but interviews in the villages often began as public events, with women and children crowding round, attracted by the novelty. However, it was usually possible to establish some degree of privacy. About three-quarters of the interviews were conducted in patients' homes and the remainder in a clinic. No problems were encountered in making tape-recordings, and 7% of the interviews were rated independently by the two Chandigarh raters. Their inter-rater reliability remained at a satisfactory high level.

The patients were generally treated on an out-patient basis, very few being admitted: 6% of the 'core' study sample were in-patients, compared with 12% of the 70 schizophrenics included in our follow-up and EE study. No patient was an in-patient for more than one month. Almost every patient was seen monthly over the course of the following year. At each visit a condensed form of the Present State Examination (PSE) (Wing *et al*, 1974) was administered, the clinician concentrating on symptoms rated as present during the index episode. Thus it was readily apparent when psychotic symptoms disappeared or, in case of relapse, when they reappeared. These detailed and meticulous records were scrutinised by an independent researcher (JL) who was blind to the EE ratings of the relatives, and who decided whether a relapse had occurred within nine months of first contact with the service, or within one year. A comprehensive follow-up at one year was built into the design of the *Determinants of Outcome* project, but it was necessary to use a nine-month follow-up as well to ensure comparability with the previous EE studies, in which patients were assessed for relapse after a period of nine months living with key relatives. However, the previous studies considered only in-patients, and their average length of stay in hospital was 11 weeks: the mean duration of follow-up from date of admission was thus close to one year, including the time spent in hospital. In some respects, therefore, the one-year follow-up of the Chandigarh patients is more appropriate than the nine-month follow-up for comparison with the data from developed countries.

Results

Diagnosis

Two diagnostic systems were employed; the CATEGO program was used to process the PSE symptoms (Wing *et al*, 1974), and a clinical diagnosis was made by the centre psychiatrists, taking into account everything that was known about the patient. The advantage of the CATEGO system is that it is highly standardised. However, it is entirely dependent on signs and symptoms elicited by use of the PSE. Some of the patients in this sample presented with an acute transient psychosis and were very difficult to interview with the PSE during their acute disturbance. When they were seen later, very few symptoms were still present. Such cases are assessed as 'doubtfully psychotic' or 'non-psychotic' when the data are processed by CATEGO, although the clinicians who saw these patients often made a firm 'centre diagnosis' of schizophrenia. Because each diagnostic system has its own advantages and disadvantages, they are used in parallel in the analyses presented here.

A total of 93 patients were included in the EE study. Of these, 78 were given a centre diagnosis of schizophrenia (Table I, first three columns). The CATEGO classes usually

2. persistent florid symptoms
3. died
4. 1 pateint had persistent florid symptoms, 1 patient had 6-month follow-up only
5. excluded for diagnostic reasons

included under the rubric 'schizophrenia' comprise S+, S?, P+, P? and O+. These classes will be referred to here as 'CATEGO SOP'. Between them they accounted for 57 of the patients in this sample (Table I, first row): 50 of these also had a centre diagnosis of schizophrenia. Another class, O?, is considered to apply to doubtful schizophrenia and has not been included in past studies of EE in England or North America, where it is rarely encountered. However, it was applied by CATEGO to 18 of the patients in this sample, 17 of whom were diagnosed as schizophrenic by the centre psychiatrists. Most of these cases presented as acute transient psychoses. Class O? accounted for more than half the cases with a centre diagnosis of schizophrenia who were not classified as CATEGO SOP. The number of patients included in each diagnostic category and the numbers excluded from follow-up for various reasons are shown in Table I.

Relapse

In the British studies, relapse was defined as Type I, the reappearance of characteristic schizophrenic symptoms after at least one month's absence, or Type II, the exacerbation of persistent schizophrenic symptoms. The judgement involved is much more difficult and subjective for a Type II relapse than for a Type I. In the study very few patients (9%) were found to have persistent schizophrenic symptoms following the key episode, and they have been excluded from the follow-up because of the difficulty of making a judgement about relapse. In the other cases, relapse was defined as the recurrence of delusions or hallucinations or the appearance of markedly disturbed behaviour after at least one month's freedom from these symptoms.

Of the 49 cases given a CATEGO SOP class and included in the EE follow-up, seven had relapsed within nine months and a further two within the year, giving a one-year relapse rate of 18%.

Of the 70 centre-diagnosed cases included, eight had relapsed within nine months and a further two within one year, giving a one-year relapse rate of 14%. It will be appreciated that a relapse rate as low as this decreases the likelihood of demonstrating significant associations of any factor with relapse. Because there are a few more relapses at one year than at nine months, and for the reasons given above concerning the duration of in-patient stay, the relapse data presented here are those for the one-year follow-up only.

Relationship between EE components and relapse

In the first-ever study of EE (Brown *et al*, 1972) the relationship between the individual components of EE and relapse were examined before constructing an index of EE. We will proceed in the same way here, since there is no *a priori* reason why the method of constructing the composite EE index in England should apply to the Chandigarh sample. We adopted the convention used in the Anglo-American studies that where two relatives in one household are assessed for EE, the higher rating on each index is used to analyse the relationship with relapse.

Critical comments and relapse

During the follow-up period one patient, who had been living with the most highly critical relatives in the sample, married and went to live with his wife who was completely uncritical. He remained well for at least a year. Taking this patient's change of household into account, and applying the British threshold for high criticism, the data are shown in Table II. It is only at the one-year follow-up and using the centre diagnosis that there is any suggestion of a relationship between high criticism and relapse, but the difference between the two relapse rates does not even approach statistical significance.

The relationship between criticism and hostility shown by Chandigarh relatives suggested that a cut-off point of three critical comments for 'high criticism' might be more appropriate (Wig *et al*, 1986b). Consequently the data were

TABLE II

Relationship between critical comments and relapse during one-year follow-up of schizophrenic patients. Two different thresholds for 'highly critical' (3 or 6 critical comments) were considered

Diagnostic group	*Number of critical comments*	*Number of patients relapsed*	*Number of patients well*	*% relapse*	
CATEGO SOP ($n=49$)	6 or more	1	6	14%	NS
	<6	8	34	19%	
Centre diagnosis ($n=70$)	6 or more	2	7	22%	NS
	<6	8	53	13%	
CATEGO SOP ($n=49$)	3 or more	3	10	23%	NS
	<3	6	30	17%	
Centre diagnosis ($n=70$)	3 or more	4	14	22%	NS
	<3	6	46	12%	

also analysed using this lower threshold (see Table II). This produced only a marginally greater difference in relapse rates between high- and low-criticism groups at the one-year follow-up, and none of the differences approach statistical significance.

Hostility and relapse

In the British studies any degree of hostility led to the relative being assigned to the high-EE group. Using this convention, the results are as shown in Table III. A significant difference in relapse rates appears within the group of centre diagnosed schizophrenics at the one-year follow-up.

Warmth and relapse

Warmth was found to indicate a good prognosis in the British studies but was not incorporated in the EE index because when it was linked with over-involvement a bad outcome ensued. As we have seen, over-involvement is rare amongst the Chandigarh relatives. The relationship between warmth and relapse is shown in Table IV.

The relapse rate in families where a relative scores 4 or more (on a 5-point scale) is half the rate in low-warmth families, but this difference is not statistically significant.

In the preceding paper it was found that relatives exhibiting both high warmth and high criticism were relatively common in the Chandigarh sample, in sharp contrast to the Danish and British samples (Wig *et al*, 1986b). Since warmth was linked with a good outcome in the British work, this combination raised the possibility that warmth might counteract the deleterious effects of criticism in Chandigarh relatives. Unfortunately there were too few patients in high-criticism homes to explore this possibility statistically. There were nine patients in high-criticism homes, two of whom relapsed. It is worth recording that while the two patients who relapsed did have relatives who were low on warmth, five of the seven patients who remained well also had low-warmth relatives. There is no suggestion from these figures that warmth might protect patients against the effects of criticism.

Over-involvement and relapse

The number of relatives scoring at least 3 on over-involvement was too few to conduct a meaningful analysis. Of the four patients with families rated high on this component, one relapsed. The patient who relapsed had a spouse with a warmth rating of 1, whereas the other three patients came from families with warmth rated as 5, 4 and 4. This suggests that, as in the British studies, warmth and over-involvement may be closely associated.

TABLE III

Relationship between hostility and relapse during a one-year follow-up of schizophrenics

Diagnostic group	*Hostility*	*Number of patients relapsed*	*Number of patients well*	*% relapse*	*Statistical significance*
CATEGO SOP ($n=49$)	Present	3	5	38%	NS
	Absent	6	35	15%	
Centre diagnosis ($n=70$)	Present	4	7	36%	exact $P=0.04$
	Absent	6	53	10%	

TABLE IV

Relationship between warmth and relapse during a one-year follow-up of schizophrenics

Diagnostic group	*Rating on warmth scale (1–5)*	*Number of patients relapsed*	*Number of patients well*	*% relapse*	
CATEGO SOP ($n=49$)	4 or more	1	10	9%	NS
	<4	8	30	21%	
Centre diagnosis ($n=70$)	4 or more	1	14	7%	NS
	<4	9	46	16%	

The possibility that over-involvement has been consistently under-rated in this study was raised in the first paper of this series (Wig *et al*, 1986a). To compensate for this potential bias it seemed sensible to lower the cut-off point for over-involvement to 2 and then re-examine its relationship to outcome; but when this was done no alteration was produced in the relationship between over-involvement and relapse.

High EE and relapse

In the current British studies, families are assigned to a high-EE category if they score 6 or more on critical remarks, or show any degree of hostility, or are rated at 3 or above on over-involvement. These same criteria have been applied to a sample of Californian relatives, and despite a significantly different distribution of critical comments from London relatives, the resulting measures of EE have proved to be as strongly linked with outcome of schizophrenia (Vaughn *et al*, 1984). Among the Chandigarh sample, only hostility was found to be significantly linked with relapse. However, there was also a tendency for excessive critical comments and over-involvement to be associated with relapse. There was no indication from the data that the criterion for high criticism should be lowered, or that warmth should be incorporated in the index as a modifying factor. Therefore the criteria used in London to assign families to high- or low-EE categories were applied unchanged to the Chandigarh data.

The relationship between high/low EE and outcome is presented in Table V. It can be seen that the relapse rates in high-EE and low-EE groups are very similar, both for cases classified as CATEGO SOP and for centre-diagnosed schizophrenics. However, it is only in the latter group that the difference in relapse rates between high-EE and low-EE homes reaches an acceptable level of statistical significance, mostly because of the larger number of patients involved.

Our results for the centre-diagnosed schizophrenics replicate the relationship between relatives' EE and outcome of schizophrenia found in the Anglo-American studies, in which face-to-face contact between relative and patient and maintenance neuroleptics were both found to modify the outcome in high-EE homes. Unfortunately the one-year relapse rate in the Chandigarh sample is too small to investigate the possible role of these factors.

Comparability of London and Chandigarh samples

There are two major differences between the centre-diagnosed schizophrenics from Chandigarh and the patients included in the London studies: the Chandigarh patients were all first contacts with the psychiatric services; and they included cases classified by CATEGO as O?, which were excluded from the London samples. To make a valid comparison between relapse rates, it is necessary to take account of these differences.

It is well documented that first-admission patients have a better outcome than patients on subsequent admissions. Therefore it is necessary to compare the Chandigarh first-contact patients with a sample of first-admitted patients from London. The studies by Brown *et al* (1972) and Vaughn & Leff (1976a) used identical techniques of clinical assessment and EE rating, so that their data can be pooled. Of their 128 patients, 77 were first admissions and are used here for comparison with the Chandigarh sample.

The nine-month relapse rate for the London first-admission patients was 29%. The comparable rate for Chandigarh CATEGO SOP cases was not significantly different, at 18%. However, the rate for the centre-diagnosed patients was 14%, significantly lower than that for the London cases ($P<0.05$). This difference could be attributable to the inclusion of CATEGO class O? patients in the centre-diagnosed sample, to the lower proportion of high-EE homes, or to both factors.

Of the 77 London patients, 36 (47%) lived with high-EE relatives. The proportion of high-EE homes in the Chandigarh centre-diagnosed sample was 23%, significantly lower ($\chi^2=9.16$, $P<0.005$). Since living in a high-EE home was significantly associated with a poorer outcome in both samples, this difference could account for the better outcome of the Chandigarh patients.

Of the 78 patients diagnosed by the Chandiagarh psychiatrists as suffering from schizophrenia, 17 (22%) were assigned by CATEGO to Class O?. Among the 24 schizophrenics from rural areas Class O? accounted for 9 (38%), among the 54 urban schizophrenics it accounted for

TABLE V
Relationship between EE and relapse during a one-year follow-up of schizophrenics

Diagnostic group	*EE level*	*Number of patients relapsed*	*Number of patients well*	*% relapse*	*Statistical significance*
CATEGO SOP ($n=49$)	High EE	4	8	33%	exact $P=0.105$
	Low EE	5	32	14%	
Clinical diagnosis ($n=70$)	High EE	5	11	31%	exact $P=0.035$
	Low EE	5	49	9%	

8 (15%): these proportions are significantly different ($P<0.05$). No patient in Class O? relapsed, compared with 19% of the remainder, but this difference is not significant. This may, of course, be an artifact of the small sample-size, but the data do not allow us to conclude that the inclusion of Class O? patients in the Chandigarh sample explains the better outcome compared with the London sample.

Influence of other factors on relapse

In all the previous studies of EE and relapse, male sex and unmarried status have been found to be associated with a poor outcome. However, after partialling out the variance due to these factors, we found that the relationship between EE and relapse remained significant.

In the Chandigarh sample the relapse rate of married patients (7%) was considerably lower than that of single patients (21%) but not significantly so. Similarly the relapse rate of women (8%) was less than half that of men (22%), but this difference was not statistically significant. It was noteworthy, however, that all seven males who relapsed were single. Considering males alone, relapse was found to be significantly higher among single men than among those who were ever married (exact $P=0.023$).

The other factor in this sample that might be expected to be associated with relapse is urban or rural domicile, since high-EE homes found significantly more often in the city than in the country ($P<0.01$) (Wig *et al*, 1986b). The urban relapse rate was 19% compared with a rural relapse rate of 9%, a difference which does not reach statistical significance although it is in the expected direction.

Thus there are a number of factors apart from EE which are marginally or significantly associated with poor outcome; male sex, single status and residence in the city. In order to determine whether any of these factors might account for the relationship between EE and relapse, a series of log-linear analyses was performed using the SAS–FUNCAT program. The model employed supposes that the logit of the probability of a relapse is a function of EE and one other variable. The variables tested with this model were: sex of patient; marital status; urban/rural domicile; diagnostic group CATEGO O?/other classes. The results of these analyses are shown in Table VI, from which it can be seen that in each case only EE is significantly associated with relapse.

Table VI

Results of testing the contribution of various factors to relapse. Each log-linear model includes EE and one other factor

	Significance
EE	$P=0.03$
Sex	$P=0.10$
EE	$P=0.05$
Urban domicile	$P=0.78$
EE	$P=0.04$
Marital status	$P=0.09$
EE	$P=0.03$
CATEGO Class O?	$P=0.24$

Considerable attention has been given in the *Outcome* study to Schneiderian first-rank symptoms and their discriminatory and predictive possibilities. Patients who manifest one or more of eight such specified symptoms rated on the PSE are assigned a CATEGO class of S+. Comparing the 27 patients in the EE study who had CATEGO class S+ with the other 53 patients, we found no significant difference between the levels of EE in the two groups: 33% of S+ patients and 16% of non-S+ patients had high-EE households. On the other hand, the relapse rate of the S+ patients (30%) was significantly higher than the 5% rate of the non-S+ patients ($P<0.006$). We also found that the association of EE with relapse was no longer statistically significant if the association with CATEGO class S+ was taken into consideration: log-linear analysis gave $P=0.02$ for CATEGO class S+ and $P=0.11$ for EE.

Relationship between life events, EE and schizophrenic episodes

In the studies carried out in London it has proved possible to study the relationship between life events and EE in the precipitation of relapse (Leff *et al*, 1983). Life events were assessed by the technique of Brown & Birley (1968). It was found that among patients who suffered an episode of schizophrenia when not taking maintenance neuroleptics, *either* independent life events *or* high EE appeared to be responsible. Independent life events exerted their effect during the three weeks or so before the onset of schizophrenic symptoms. In a study conducted by Leff & Vaughn (1980), 9 out of 16 (56%) patients who were off medication and living with low-EE relatives experienced an independent life event in the three weeks before relapse. The corresponding proportion for those in high-EE homes was one out of 15 (7%), a highly significant difference (Exact $P=0.004$).

It is possible to conduct a similar analysis on the Chandigarh sample of first-contact patients in order to study the relationship between life events, expressed emotion and onset of schizophrenic disorder. One of the sub-studies being carried out as part of the *Determinants of Outcome* project concerns the prevalence of life events prior to the sudden onset of an episode of illness (Day *et al*, in press). The technique of measuring life events is basically that of Brown & Birley (1968) with certain modifications to aid its cross-cultural application. Hence the data on life events from the Chandigarh centre are comparable with those from the London studies. Unfortunately not all the patients in the EE sub-study were eligible for inclusion in the life-events sub-study, but the overlap is sufficient to allow a statistical analysis.

In all, 44 patients in the EE sub-study had a life-events interview completed. Seven of these were on neuroleptic drugs when first seen: this group is too small for analysis. It is worth noting, however, that none of these patients lived in high-EE homes and that four experienced life events in the 3 weeks preceding onset. Of the remaining 37, seven were living in high-EE homes and 30 in low-EE homes. The life-events data for these patients are shown in Table VII, with the London figures for comparison. It can be seen that the

TABLE VII
Relationship between EE and life events in the three weeks before onset for patients off medication

	Patients with life event	*Patients without life event*	*Proportion with event*	*Statistical significance*
Chandigarh				
High-EE home	1	6	14.3%	$P=0.05$
Low-EE home	17	13	56.7%	
London				
High-EE home	1	14	6.7%	$P=0.004$
Low-EE home	9	7	56.3%	

proportions in each group in the Chandigarh sample are similar to the proportions in the London sample, and that the effect of events in Chandigarh just reaches significance.

Discussion

This study has supplemented the findings of the *International Pilot Study of Schizophrenia* (WHO, 1979) by showing that a cohort of first-contact patients in Chandigarh had a significantly better outcome after one year than a comparable sample in London. This result is most unlikely to be due to selection factors since strenuous efforts were made to include all instances of a first contact with the psychiatric services for schizophrenic illness within the Chandigarh centre's catchment area.

The significant association between high-EE attitudes and relapse of schizophrenia established in studies in London and California has been replicated in Chandigarh. It is remarkable that the same cut-off points on the EE scales that best predicted relapse and non-relapse in the Anglo-American studies also applied to the Chandigarh sample. This predictive validity across disparate cultures is particularly surprising in view of the markedly different distributions of EE components in the different cultural groups. It is of considerable interest, however, that hostility contributed most of the predictive validity of the EE scale in the Chandigarh sample, and that it was the only predictive component that occurred with similar frequency among North American, British, Danish and North Indian relatives. This suggests that the expression of anger in the form of hostility is relatively unmodified by cultural factors and has a similar effect on schizophrenic patients regardless of their cultural background.

Two other factors were found to be significantly associated with relapse in these North Indian patients. The first was the presence of Schneiderian first-rank symptoms, corresponding to CATEGO class S+. This was not expected, since previous studies have not found Schneideran symptoms to be of value in predicting outcome (e.g. Radhakrishnan *et al*, 1983). Furthermore, in the study of Vaughn & Leff (1976a) the relapse rate of S+ cases (27%) was not significantly different from that of other CATEGO schizophrenics (36%). Elucidation of this link between CATEGO class S+ and outcome must await further analysis; it may be an artifact of the small numbers of patients involved. The only other factor we found to have a significant association with relapse in the Chandigarh sample was single status among male patients.

Log-linear analyses demonstrated that, except for the presence of Schneiderian symptoms, none of the intervening variables studied could account for the significant association between EE and relapse. This replicates the findings of the earlier Anglo-American studies. It was somewhat surprising that no significant difference emerged between urban and rural relapse rates, since there were striking differences in the distribution of EE components between city dwellers and villagers. It is possible that a difference might be revealed with the accumulation of a larger number of relapses over the period of the two-year follow-up, which remains to be analysed.

The significant association between EE and relapse found in this Chandigarh first-contact sample, and the significantly lower proportion of high-EE households than in a comparable London sample, indicate that relatives' EE could definitely be a major factor in explaining the better outcome of the North Indian patients. This raises interesting questions about cultural influences on the emotional attitudes that are represented by the EE index.

The starting point for further studies could well be the major difference in distribution of EE components between urban and rural relatives. The possible insights afforded by this line of enquiry could contribute to therapeutic endeavours to alter the emotional environment in high-EE homes (Leff *et al*, 1982).

The overlapping data from this sub-study and the life-events sub-study have indicated a similar relationship between life events and relatives' EE to that found in the study of Vaughn & Leff (1976a): independent life events appear to play an aetiological role in the onset of schizophrenia for a substantial proportion of unmedicated patients living with low-EE relatives in Chandigarh.

The data presented in this series of three papers illustrate the feasibility and importance of conducting psychosocial research in a variety of cultural settings. Given the necessary coordinating and training facilities, work of this nature can elucidate which social factors in the pathogenesis of psychiatric conditions transcend culture and which are moulded by the cultural milieu.

Expressed Emotion in Individual and Family Settings: A Comparative Study

G. I. SZMUKLER, R. BERKOWITZ, I. EISLER, J. LEFF and C. DARE

Expressed emotion ratings were performed, in two separate settings, on the parents of 20 children suffering from anorexia nervosa. Ratings were made on conventional individual interviews and on videotapes of a family interview. Comparison of ratings in the two settings showed a very high correlation for 'critical comments'. Findings on the other scales were harder to interpret, but significant correlations as well as differences were noted. Expressed emotion rated in family interviews provides new possibilities for the study of families.

The measure 'expressed emotion' (EE) has proved reliable and valid in predicting relapse in both schizophrenia and depression (Brown *et al*, 1972; Vaughn & Leff, 1976*a*; Vaughn *et al*, 1982) and also for early termination of psychotherapy, particularly family therapy, in anorexia nervosa (Szmukler *et al*, 1985). It is a measure of relatives' attitudes to a patient, and is estimated on the basis of a standardised interview with each relative. Of the five scales rated, 'critical comments' (CC) and 'emotional over-involvement' (EOI) are the most powerful predictors. Family interventions which have resulted in a reduction of relatives' EE have also reduced the relapse rate in patients with schizophrenia (Leff *et al*, 1982).

It is assumed that EE, thus assessed, has some relationship to interactions in the family, but this has been little studied. Valone *et al* (1983) found a significant relationship between parental criticism on individual interview (rated in the conventional EE manner, but not on the standard Camberwell Family Interview) and critical statements made during direct interactions between parents and their disturbed, non-psychotic adolescent offspring. Critical statements, 'benign' or 'harsh' in quality, were rated from transcripts of videotaped dyadic interviews (parent and offspring) and triadic interviews (both parents and offspring), according to a previously devised method for assessing 'affective style' (Doane *et al*, 1981). High-EE parents made significantly more critical statements in direct interaction with their child than low-EE parents. No significant difference was found between high-EE and low-EE parents in the number of 'neutral instrusive statements' (a possible analogue of emotional overinvolvement) in direct interactions. In fact, only one of the 52 parents in the study was classified as high-EE on the basis of EOI alone.

Valone *et al* (1983) also examined the combined effect of both parents' EE on 'affective style' in direct interaction. 'Dual' high-EE parents made, in total, more critical statements than 'mixed' parents (one with high EE, the other with low), who in turn made more than 'dual' low-EE parents. It was noted, however, that in the 'mixed' parental groups the low-EE parent, when present, seemed to exert an ameliorating effect on the number of 'harsh' criticisms made, but that the number of 'benign' criticisms was the same as for dual high-EE families.

Miklowitz *et al* (1984) compared EE ratings of key relatives of patients with schizophrenia estimated from the Camberwell Family Interview (CFI) (Brown & Rutter, 1966; Vaughn & Leff, 1976*b*) with measures of 'affective style'. These were made from transcripts of audiotaped family discussions involving the patient and his parents. A significant association was found between parental high EE and a negative affective style', derived by summing critical and negative intrusive statements. There was also a relationship between the type of high EE of the parent and the type of negative 'affective style'; those with high CC made more 'critical statements', while those with high EOI made more 'negative intrusive statements'.

These studies thus support a correspondence between EE measured in an individual interview and analogous parental behaviour in direct interaction with the disturbed offspring.

The aim of the research presented here was to assess whether parental EE, estimated conventionally in an individual interview, would show a relationship to EE derived using identical scales but estimated in a family interview with all members of the family present. The families in this study all contained a patient with anorexia nervosa.

Method

Subjects

The subjects were 20 intact families, each with a young member suffering from anorexia nervosa. The patients, three of whom were males, were all admitted to the Maudsley Hospital. The mean age of the patients was 19.4 years (s.d. 3.7), the mean age of onset of their illness 16.0 years (s.d. 3.7), and the mean duration of the illness 42 months (s.d. 29). At the time of admission the patients weighed a mean of 65% (s.d. 10%) of the standard weight for their age and height. Three patients had developed bulimia nervosa as a sequel to anorexia nervosa. Eleven of the families were of social class I or II, and a further seven from social class III (Registrar-General's classification, based on father's occupation). Nine parents had a history of psychiatric disorder – usually neurotic depression.

Individual ratings of EE

During the patient's stay in hospital both parents were interviewed separately, using the abbreviated version of the CFI. All five scales of EE were rated from audiotapes of these interviews. These scales comprised 'critical comments' about the patient (a simple count), 'hostility' (0–3), 'emotional overinvolvement' based on expressions by the parent of overprotectiveness, overconcern and exaggerated emotional responses (0–5), 'warmth' (0–5), and 'positive comments' (a simple count). The ratings are based not only on content but also on the vocal aspects of speech, such as tone and pitch.

Family ratings of EE

All of the families participated in a 'picnic lunch' at the end of the hospital stay or shortly afterwards, which was videotaped. All members of the family were invited, and in nine cases one or more siblings were present in addition to the parents and patient. These sessions were not designed for the purposes of this study, but for another research project: examining patterns of family interaction through direct observation. Nor were they intended as therapy sessions, although they were conducted by a therapist.

A fairly loose structure was imposed. In the first half of the session the therapist was asked to discuss in a neutral way the family's normal eating behaviour (e.g. who prepares the food, when do they normally eat, who is present, food preferences). The patient's eating disorder was also discussed, with the therapist adopting a simple fact-finding approach. In the second half of the session pressure was exerted by the therapist on the parents to encourage the patient to eat. The intention was to examine the way in which the family responded to this stress-inducing intervention. The sessions lasted one hour. Sessions did not always run according to plan, particularly as different therapists exerted differing amounts of pressure in the second phase, but in every case, the family found the situation a strain.

TABLE I

Comparison of family and individual EE ratings

	Individual EE score		*EE score in family setting*		*Correlation of ratings in the two settings*[1]	*Significance*[2] *of difference* of mean scores ($P<$)

2. Wilcoxon signed rank test

The videotapes of the sessions formed the material for our EE ratings in the family setting. The decision to use them for this purpose was not taken until after they had been made, and the therapists were not aware of the parents' individual EE ratings. The EE ratings were made by RB, who was blind to the individual ratings. Ratings were made for each parent on all five scales, but only concerning attitudes expressed about or to the patient.

Results

Table I summarises the main findings for four of the scales rated. The fifth scale, 'hostility', was excluded from the analysis because so few parents scored on this, in either situation, that a comparison was not meaningful.

Critical comments

A strong correlation was found between ratings of CC in the two settings for both mothers and fathers. The degree of association of the two sets of ratings is best seen in a scattergram (Fig. 1). The correlation of +0.8 is as high as the correlations found between trained raters, rating the same audiotape in the conventional manner. The overall level of criticism in the two situations did not differ, but mothers were significantly more critical than fathers in both situations. Using the commonly adopted cut-off point of 6+ for a classification as 'high' EE results in an identical classification of 18 of the 20 mothers in the two settings (Fig. 1). With the same cut-off point, only three fathers are classified differently in the two settings, but this is somewhat misleading, as few fathers scored 6 or more in either situation. The application of a lower cut-off point for fathers in this population is discussed elsewhere (Szmukler *et al*, 1985).

Emotional over-involvement

Overall there was a significant though modest correlation between the ratings of EOI in the two settings. Fathers obtained significantly higher ratings in the family interview. A similar trend was found for mothers, but the difference was not as clear, and did not reach statistical significance. Emotional overinvolvement also showed different associations with other measures when the two settings were compared. A significant correlation ($r=0.48$) was found between EOI and CC in the family setting, but not in the individual setting. Fathers' and mothers' EOI ratings showed a strong correlation with each other in the family setting ($r=0.60$), but not in the individual settings ($r=0.12$).

Warmth

A high correlation was found for mothers' ratings of warmth; fathers' ratings correlated only modestly, and did not reach statistical significance. Both fathers and mothers, however, were rated as being significantly warmer in the individual interviews. In both settings, mothers' and fathers' ratings were strongly correlated with each other (family interview $r=0.59$; individual interview $r=0.51$).

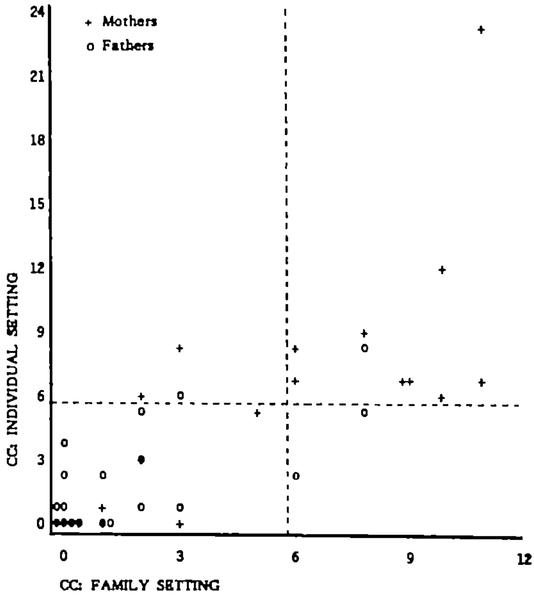

FIG. 1 Critical comments by mothers and fathers in the two settings.

Positive comments

The ratings for this scale did not correlate significantly between the two settings, but again both fathers and mothers made significantly fewer positive comments (PC) in the family session than in the individual interview. Ratings of mothers' and fathers' positive comments were strongly correlated with each other in the individual setting ($r=0.56$), but not in the family setting ($r=0.13$).

Discussion

In evaluating the results of this study, a number of general points should be borne in mind. The family interviews on which EE ratings were made were not structured to the same degree as the CFI. The conductors of these sessions were following a general plan, but it was followed to varying degrees. In contrast to the individual interviews, the parents were put under considerable pressure during the latter part of the family sessions. Although these sessions lasted about the same time as the individual interviews the parents spoke less, since they shared the floor with each other, with the patient, and often with the patient's siblings as well.

The method of rating EE in the family sessions, although based on the usual principles and definitions, required new circumstances to be taken into account. Direct comments to, as well as about the patient were rated (although the former were uncommon) and, as the ratings were made from videotapes rather than audiotapes, visual cues were also available. However, the rater felt that such cues did not substantially influence her ratings, and the content of speech and tone of voice still provided the principal basis for the ratings. Although high reliability is achieved between trained raters of EE on individual interviews on audiotapes, it is not known whether comparable results can be achieved on family interviews on videotape.

Our sample was restricted to families with an anoretic youngster, and as it is possible that such families have certain characteristics in common (Minuchin *et al*, 1978) which may not appear to the same extent in other families, our results cannot automatically be generalised to other groups.

In the light of these points, the correlation for CC between the two settings is remarkably high. Perhaps more remarkable still is that the absolute number of CC was as high in the family setting as in the individual one. These findings strongly support the reliability of this rating, and demonstrate that CC noted in individual interviews also occur in the course of family interactions without any attenuation of frequency.

In contrast to the clarity of the results concerning CC, those for EOI are more difficult to interpret. Correlations were modest, and there were significant differences in the levels rated in the two conditions, these being higher (especially for fathers) in the family setting. Two major lines of explanation can be invoked for this. The first is that the inter-rater reliability was low, possibly because of the novel application of EE ratings in a family setting. If this is not the case, then the results suggest that EOI changes across the two situations studied here. The fact that EOI was positively correlated with CC in the family setting but not the individual setting might suggest that different components were being rated, but it is also possible that in the family situation EOI had a relationship with CC which was somehow a product of that situation. For these issues to be resolved, further studies are required; the first point to be examined must be the reliability of EOI ratings in a family setting.

Mothers' warmth was significantly correlated for the two settings, but it was also significantly less in the family setting. Fathers' warmth was not correlated, but again was significantly less in the family setting. Time might have been a factor here, since there might have been fewer opportunities for individuals to express positive feelings in the family interview. We do not believe, however, that this is the main reason for the reduction of warmth. Discussions between the authors, after the experiment, of the ratings for individual parents across the two settings suggested that they were reliable, and that the family setting itself seemed to inhibit warmth. This is also supported by the finding that 'positive comments', another component of positive feelings about the patient, were also significantly fewer in the family interviews. If warmth is less evident in the family setting, it may be asked whether this represents a general characteristic of all families or one specific to families with an anorectic youngster, reflecting a particular family dynamic. This question merits further study.

The results of our study lend support to those of Valone *et al* (1983) and of Miklowitz *et al* (1984), showing a significant correspondence between criticism in the individual EE interview and in family sessions. Whereas the former studies relied on transcripts of family sessions, thus excluding the contribution of 'tone', ours has included this, and has shown that very high correlations can be obtained. The robustness of the rating of criticism is extraordinarily good, judged by the standards of psychological measures. It stands up well even when estimated in quite dissimilar settings, and whether measured directly or on the basis of transcripts of interviews. If its predictive abilities in other disorders are as good as for relapse in schizophrenia or dropping out of therapy in anorexia nervosa, then we have a valuable measure – even more so if it is amenable to change through directed therapeutic interventions.

The value of the other scales of EE is less well defined, but when applied in a family setting may prove fruitful in the elaboration of 'hypotheses' about how particular families or groups of families function. Expressed emotion may thus provide a much needed reliable basis for describing patterns of family interaction.

At present EE is seldom used in clinical practice, in spite of its obvious potential. This is due in part at least to the time-consuming nature of arranging separate individual interviews and to the less apparent relevance of such interviews for those engaged in family work. Ratings based on observation of family sessions, videotaped or live, may overcome some of these obstacles.

When depression is the source of anxiety...

PROTHIADEN

Dothiepin Hydrochloride B.P.

restores peace of mind

ifferential diagnosis of depression and anxiety is rarely clear cut. Your typically middle-aged female atients will usually present with symptoms of both. The potential risks of an inappropriate choice of reatment for these patients can often be a cause for concern.

rothiaden, with its well-proven ability to relieve both depression and anxiety, can alleviate this oncern. A prescription for Prothiaden ensures that neither aspect of your patients' problem is left ntreated.

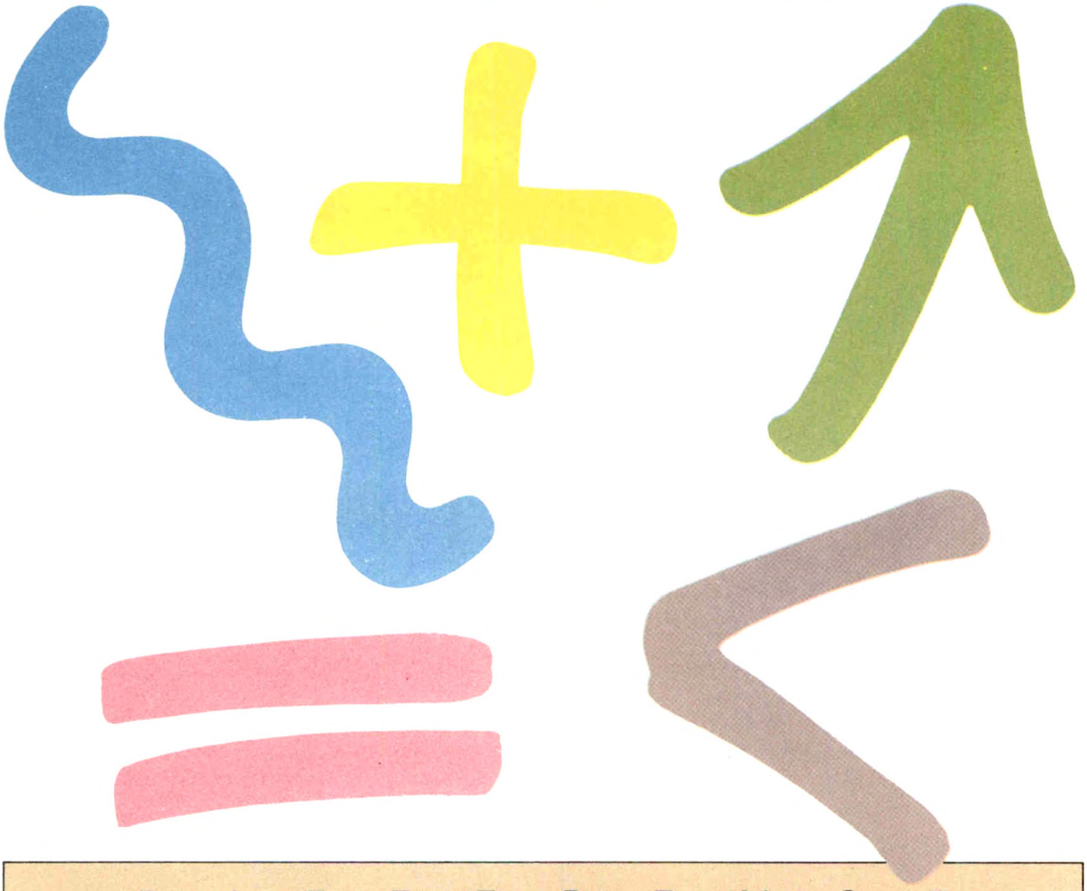
o, in this complex diagnosis, Prothiaden has an additional benefit – relieving your anxiety as well s that of your patients.

RESCRIBING INFORMATION

resentation: Prothiaden is Dothiepin Hydrochloride B.P an antidepressant of the tricyclic group. It is available as 25mg capsules and 75mg tablets. **Uses:** Prothiaden is ndicated in the treatment of depression and associated anxiety. **Dosage:** Prothiaden should be given in a dosage of 75 to 150mg daily, based on response and severity. This may e taken as a single evening dose. In certain circumstances, i.e. in hospital use, Prothiaden has been given in dosages up to 225mg daily. Elderly – half the normal dose may be ufficient. **Precautions and Contra-indications:** Prothiaden has anticholinergic properties, therefore, it may precipitate urinary retention in susceptible individuals and its use hould be avoided in patients with existing or potential urinary retention. Prothiaden should not be used in patients with closed-angle glaucoma. Caution is advised when treating pileptic patients and those with cardiovascular disorders. Prothiaden should not be used with MAO inhibitors nor within 14 days of ceasing such treatment. It may modify the ction of some CNS depressants, catecholamines and hypotensive agents. **Side Effects:** These are usually mild and normally controlled by reducing the dosage. The following ave been reported: dryness of mouth, constipation, disturbed accommodation, orthostatic hypotension, palpitations, somnolence, tremor, headache. **Basic N.H.S. Price:** 28 x 5mg £4.00 as at 1st Nov 1986. **Product Licence Numbers:** PL0014/5941. PL0014/0209. ® The Boots Company PLC. Nottingham, England. Further information available n request.

THE DEPIXOL

cis(Z)-flupenthixol decanoate



DIFFERENCE

= Proven antipsychotic effect (1-7)

↑ Restores mood (1-3)   ~ Dosage flexibility   < Cost-effective therapy (8)

PRESCRIBING INFORMATION

Depixol Injection and Depixol-Conc. Injection contain cis(Z)-flupenthixol decanoate, 20mg per ml and 100mg per ml respectively, in thin vegetable oil.
Indications Psychoses, especially schizophrenia, particularly where there are associated features of withdrawal, inertia or apathy.
Dosage and Administration By deep intramuscular injection, 1-2ml every 2-4 weeks, to a maximum of 400 mg weekly. Children: Not recommended for children.
Side Effects Early (frequent) and late (rare) dyskinesias. Extrapyramidal effects sometimes require dose reduction or anti-Parkinson drug treatment.
Contra-indications Not recommended for overactive patients, or for those with Parkinsonism, severe arteriosclerosis, senile confusional, or advanced renal, hepatic, or cardiovascular disease, intolerance to other neuroleptics, pregnancy.
Further Information Overdosage should be treated; (a) by anticholinergic anti-Parkinson drugs if extrapyramidal symptoms occur, (b) by sedation (with benzodiazepines) in the unlikely event of agitation or excitement, (c) by noradrenaline in saline intravenous drip if the patient is shocked.
Package Quantities & Basic NHS Prices Boxes of 10 x 20mg (1ml) £15.53, 10 x 40mg (2ml) £25.99, 10 x 100mg (1ml) ampoules £59.53, 5 x 20mg and 5 x 40mg syringes £8.51 and £13.74, 1 x 200mg (10ml) and 1 x 500mg (5ml) vials £14.74 and £28.27.

The Impact of Recent Undesirable Life Events on Psychiatric Disorders in Childhood and Adolescence

I. M. GOODYER, I. KOLVIN and SONIA GATZANIS

The timing and number of recent stressful life events occurring in the year before onset of emotional or behavioural disorder was examined in a consecutive sample of children. Overall, events increase the relative risk of psychiatric disorder by 3–6 times. Events occur throughout the 12 months, but tend to cluster in the 16 weeks nearest onset of symptoms. The number of events influences the onset of disorder: cases with multiple events are more likely to have an event within 16 weeks of onset; cases with single events are more likely to have the event 36–52 weeks before onset. Cases whose onset occurs within 4 weeks of an event may have experienced single or multiple events. The results support the concept of additivity of recent stressful events in some cases of emotional and behavioural disorders in childhood.

Recent research indicates that recent undesirable life events which are independent of illness onset and carry a severe degree of negative impact (undesirability) may have a causal association with the onset of psychiatric disorder in children and adolescents (Goodyer *et al*, 1985*a*). Studies on adults, using general population controls, consistently indicate important effects, with the risk of psychiatric illness being increased by 2–7 times in the six months after an event (Paykel, 1978; Cooke & Hole, 1983). In addition Brown & Harris (1978), in their major study on depression in women, showed that severe events lead quickly to depression – most often within 9 weeks, and for the great majority within 6 months. However, these authors suggested that severe events may have even longer-term effects.

Brown & Harris (1978) also examined the effects of experiencing single or multiple undesirable life events in the year prior to onset, and concluded that multiple unrelated events had an additive effect, thereby increasing the risk of becoming depressed. However, they pointed out that only one in five of depressed women experienced two or more such unrelated events.

Since our data (Goodyer *et al*, 1985*a*) was derived from a case-control study and can be expressed in 2 × 2 contingency tables, we felt that: (a) use of relative risk (odds) was an appropriate and convenient way of estimating the effect that events exert on psychiatric illness in childhood and adolescence (see Appendix 1); (b) the dating of when life events occurred prior to onset would allow us to examine whether events have predominantly short or long-term effects over the 12-month period; and (c) comparing children who had experienced single and multiple events would allow us to examine the concept of additivity.

Method

Full details of the method are available elsewhere (Goodyer *et al*, 1985*a*). The study used a case-control design, and compared a consecutive sample of children attending a child psychiatry clinic with a group of community subjects drawn from the same area.

Subjects

The psychiatric sample consisted of 157 school-aged children and adolescents. The cases were classified into four mutually exclusive clinical groups according to the predominant presenting signs and symptoms obtained from the clinicians' routine assessments:

(a) conduct disorders: presenting with predominant symptoms of antisocial behaviour such as stealing, cruelty, destructiveness, or bullying ($n = 44$)
(b) mild emotional disorders: presenting with predominant symptoms of mild anxiety. This group includes transient states of anxiety, fearfulness and misery, adolescent rebellion, and parasuicide in the absence of other psychiatric disturbance ($n = 55$)
(c) severe emotional disorders: presenting with predominant symptoms of depression and serious neurotic symptoms. This group includes depression, phobic and obsessional states, school refusal, and suicide attempts ($n = 32$)
(d) somatic disorders: presenting with predominant physical symptoms. This group includes vague aches and pains, monosymptomatic hysteria, complex medical problems, (e.g. diabetes or asthma), and

secondary encopresis and enuresis occurring in the absence of any other predominant clinical features ($n = 26$).

The name, sex, date of birth, and school was recorded for each case and a table of random numbers used to select 50% of this sample. These subjects were attending 36 schools from three educational areas (City of Newcastle, North Tyneside, and Northumberland).

Following agreement with each of the Directors of Education a pool of controls was obtained by asking head teachers to provide the names and addresses of three children of the same age and sex and attending the same school for each child referred to the unit. A letter was sent to the first name listed in each group requesting an interview. Of the 78 approached, 72 (92%) agreed to the interview. Four 'reserves' were obtained for the 6 refusals by writing to the second or third names listed; the control sample thus consisted of 76 children. For the analyses presented in this paper the community controls were used as a single group, so that the base rate of events in the controls remained constant in any comparisons with the clinical groups.

The control group was compared with the psychiatric group as a whole and with the four clinical subgroups for age (using Student's *t*-test), sex, and social class (using chi-squared). There were no significant differences for any of these analyses.

Collection of life events

A schedule for recent life events was developed, and administered as a semi-structured interview to mothers or mother surrogates of subjects. For psychiatric cases the onset of illness was carefully established. Only events that occurred in the 12 months before illness in cases, or before the date of interview for controls, were included. Events received two ratings according to criteria described by Paykel (1983): independence and objective negative impact, both rated on a five-point scale. Only events considered independent or probably independent of illness and carrying a moderate to severe impact were used in the analysis.

Results were expressed as the proportion of cases experiencing events over monthly periods prior to onset of disorder. We have previously reported that the numbers of specific types of events are rather low (Goodyer *et al*, 1985*a*); the results in this paper therefore include all events carrying a moderate to severe degree of negative impact. Where appropriate the chi-squared test has been used to look for differences between cases and controls and between clinical groups. Relative risk has been estimated where appropriate, according to the formula described by McMahon and Pugh (1970) and used by Paykel (1978) (see Appendix 1).

Results

Characteristics of the clinic sample

Of the 157 patients, 68 (43%) were girls and 89 (57%) were boys. The age range was 4.7–16.25 years (mean = 11.4, s.d. = 2.8 years). The influence of age and sex on the association between recent life events and psychiatric disorder are considered elsewhere (Goodyer *et al*, 1986).

Recall of events

One method of testing the reliability of reporting events is to examine the fall-off in the mean number of events per month

TABLE I

The monthly distribution of cases by (a) event nearest to onset of disorder, (b) cases with only one event, and (c) cases with more than one event

	Number of months from onset											
	12	*11*	*10*	*9*	*8*	*7*	*6*	*5*	*4*	*3*	*2*	*1*
Event nearest onset ($n = 96$):%	9.3	7.3	5.2	7.3	8.3	4.2	4.2	5.2	11.5	5.2	10.4	21.9
		29.1				21.9					49	
Cases with only one event ($n = 54$):%	14.8	9.3	7.4	13.0	9.3	5.5	5.5	3.7	5.5	1.85	7.4	16.7**
		44.5***				24†					31.5*	
[1]Cases with 2 or more events ($n = 42$):%	2.4	4.8	2.4	0	7.1	2.4	2.4	7.2	19	9.5	14.3	28.5**
		9.6***				19.1†					71.3*	

1. Arranged by event nearest to onset of disorder.
*$\chi^2 = 15.08$, d.f. = 1, $P < 0.001$
**$\chi^2 = 2.109$, d.f. = 1, NS
***$\chi^2 = 13.944$, d.f. = 1, $P < 0.001$
†$\chi^2 = 0.349$, d.f. = 1, NS

recalled by subjects as times further in the past are considered. In the general population such events should be randomly distributed in time. If there is a large fall-off (greater than 5% per month) there may have been a serious under-reporting of events. Taking all controls ($n = 76$) as a single group, the fall-off per month in our sample was less than 1% – an acceptably low rate and in line with adult studies using interview techniques (Paykel, 1983). We conclude that it is unlikely there has been serious under-reporting of moderate to severe events.

Presence of events

Of the 157 patients, 96 (61%) experienced one or more moderate to severe events in the 12 months before the onset of illness; 54 (34%) had only one event, compared with 13 (17%) of the controls ($\chi^2 = 7.472$, d.f. = 1, $P < 0.01$), and 42 (27%) had two or more events, compared with 4 (5%) controls ($\chi^2 = 14.923$, d.f. = 1, $P < 0.001$).

If severe events make an important contribution to disorder there should be a rise in risk. Events were experienced by 27, 35, 17, and 17 patients in the groups with conduct, mild emotional, severe emotional, and somatic disorders respectively. This gives relative risk factors for these groups of 5.5, 6.1, 3.7, and 6.5 respectively.

Timing and number of events

The speed with which stressful events exert their effects on the onset of disorder cannot be established from a 2 × 2 contingency table, as all such events over the 12 months are included. In order to examine whether or not events exert long or short-term effects, the distribution of the events nearest onset for each case was established. However, if a patient had more than one event there was no way of deciding whether symptoms were brought on by a single-event. The distribution of cases experiencing only one event was therefore examined. Finally, if a greater proportion of cases experiencing multiple events have their final event nearer onset than cases with only one event, it may be that there is some additive effect of events. Table I shows the three distributions.

Onset of symptoms within 16 weeks of an event was experienced by 49% of all cases. The proportion of single-event cases experiencing an onset within 16 weeks was 31%, compared with 71% of multiple-event cases ($\chi^2 = 15.08$, d.f. = 1, $P < 0.001$); there is thus a significant association between multiple events and onset of disorder within 16 weeks of the final event.

An event occurring within 4 weeks of onset of disorder was denoted as having a 'rapid' effect. This was experienced by 21.9% of all patients. 16.7% of single-event cases experienced a rapid effect, compared with 28% of multiple-event cases ($\chi^2 = 2.109$, d.f. = 1, NS). Patients with an onset within 4 weeks of their last event, therefore, may equally have experienced single or multiple events in the previous 12 months.

A 'long-term' effect was defined as onset of symptoms occurring 36–52 weeks after the last event. This was experienced by 29.1% of all cases, accounted for by 44.5% of single-event cases and 9.6% of multiple-event cases ($\chi^2 = 13.944$, d.f. = 1, $P < 0.001$). Patients experiencing a long-term effect from events are therefore more likely to have experienced one event only.

Examination of events occurring 17–35 weeks before onset shows that 22.9% of cases experience onset of symptoms after this period; these are accounted for by 24% of single-event cases and 19.1% of multiple-event cases ($\chi^2 = 0.349$, d.f. = 1, NS). Thus there is no significant association with this period and number of events.

The timing of events for all community subjects was also examined. Numbers are small: only 22% of controls experienced one or more moderate to severe events. Of these 23.5% were multiple events and 76.5% single events. Thus, division into time periods by single and multiple events is impractical. If all controls are taken together, 8% had events within 16 weeks, 6% between 17 and 35 weeks, and 8% between 36 and 52 weeks. Comparison with all cases for each time period resulted in significant differences. Thus an excess of cases experiencing one or more events occurs throughout the 12 months.

Events therefore exert long-term (over 36–52 weeks), short-term (over 16 weeks), and rapid (over 4 weeks) effects on the onset of psychiatric disorder. Short-term effects are more likely in multiple-event cases, whereas long-term effects are more likely in single-event cases. Events exerting rapid effects can occur in either single or multiple-event cases.

TABLE II

The proportion of subjects experiencing one or more moderate to severe events at 4-monthly periods preceding onset of illness for cases or day of interview for controls, expressed as a percentage of cases with at least one event

		No. of weeks before onset					
		52–35		*35–17*		*16–1*	
	n	*n*	*%*	*n*	*%*	*n*	*%*
Conduct	44	5	11	12	27	10	23
Mild mood	55	10	18	10	18	15	27
Severe mood	32	7	22	4	13	6	19
Somatic	26	7	27	5	19	5	19
Controls	76	6	8	5	6	6	8

Specificity of events and diagnosis

The results so far consider the impact of events on all psychiatric cases. However, we have previously reported the association between events and four classes of psychiatric disorder: conduct, mild mood, severe mood, and somatic (Goodyer *et al*, 1985). We therefore divided the psychiatric sample into these four groups, to examine two questions:

(a) is the proximity of events nearest onset different between clinical groups?

TABLE III

The proportion of subjects experiencing 'single' or 'multiple' moderate to severe events in the 12 months prior to onset of illness for cases or day of interview for controls

		Single event		*Multiple event*	
	n	*n*	%	*n*	%
Conduct	44	11	25	16	36
Mild mood	55	20	36	15	28
Severe mood	32	12	37	5	16
Somatic	26	12	46	5	19
Controls	76	13	17	4	5

(b) is there any specificity between multiple events and any clinical group?

Table II examines short or long-term effects for undesirable events for each clinical group. The numbers of cases are too small to present the results as in Table I, and refer to all cases in each group experiencing one or more events. The results show that events exert short and long-term effects for all four diagnostic groups. Only mild mood disorders show any increase in cases experiencing events in the 16 weeks closest to onset, where 27% have an event nearest onset compared with 18% in the previous time periods.

Furthermore, 22% of severe mood and 27% of somatic cases occur with events occurring 35–52 weeks from onset. Although this is an increase in this time period for both disorders the differences are not significant.

The relative risk was calculated for each time period (comparing cases against controls) and the odds were the same magnitude for each time period within each clinical group as compared with events over all the 12 months.

Table III shows subjects divided into single and multiple event groups. The proportion of cases experiencing single events are highest for somatic disorders (46%) and lowest for conduct disorder (25%), with mild and severe mood showing similar rates (36% and 37%). The proportion of cases experiencing multiple events are highest for conduct disorders (36%) and lowest for severe mood (16%) and somatic disorders (19%) with mild mood in between (28%). All four clinical groups show significantly higher rates of both single and multiple events compared with the community controls. However, there are no significant differences in rates between the clinical groups. Thus there appears to be no specificity between multiple events and type of disorder.

Discussion

The results suggest that life events carrying a moderate to severe degree of negative impact (undesirability) exert effects of some importance. Thus the risk (odds) of developing a psychiatric disorder presenting with conduct/emotional symptoms is increased by a factor of 3–6 in the 12 months after exposure to an event. The lowest risk appears to be for severe mood disorders; however, the proportion of cases with severe mood disorder is only 10% less than for other cases. It may be that events exert a smaller degree of risk for severe mood disorders compared with other clinical groups, but this statement requires confirmation.

The distribution of events in the 12 months prior to onset is of interest for two reasons. Firstly, events occur throughout the 12 months, indicating that moderate to severely undesirable events exert long-term, short-term, and rapid effects on the onset of psychiatric disorder. Secondly, there are different associations between events and disorder according to the timing and the number of events. Thus nearly three-quarters of multiple-event cases experienced an event in the short-term (i.e. 1 to 16 weeks before onset of symptoms) compared with only one third of single-event cases. Clearly, not only multiple-event cases experience a short-term effect; however, the findings suggest that previous *recent* stresses increase the likelihood of experiencing an event in the 16 weeks before onset of illness. This suggests that for some cases (19% in this study) an additive effect is occurring between recent events over the 12-month period.

When considering rapid effects of events, the number of recent events appears unimportant. Thus in acute crises (i.e. symptoms occurring immediately and up to four weeks after an event) symptoms are partially or totally dependent on the effects of a single event but occur in multiple-event cases.

Interestingly, single-event cases occur throughout the 12 months period, with almost half of the cases experiencing their event 36–52 weeks before onset, i.e. a long-term effect. Furthermore, long-term effects are more likely to be associated with experiencing a single event and few multiple-event cases (less than 10%) experience their event nearest onset in this time period.

These results suggest that the mechanisms by which events exert their effects are likely to be different and depend to some extent on their number and timing. Possible mechanisms can be considered according to the three differences in timing already described. Thus, for the long-term effects of single events:

(a) the effects may be a result of buffering factors antedating the event and influencing its impact. Such buffering factors may occur in the child's social supports or family relationships (Rutter, 1985)

(b) the nature of the event may be such that protective factors are activated subsequent to the event, e.g. serious illness, family loss, or death may mobilise support for the child
(c) the salience of the event may be important. Thus, an event may not be fully understood at the time of occurrence and its personal meaning and impact may not become explicit until later.

These potential mechanisms merit further study.

As indicated, the short-term effects of multiple-events suggest an additive effect. Whether this additivity is a non-specific quantitative effect or contains qualitative factors is not clear. In studies on adult depressed women Brown & Harris (1978) found evidence for additivity only for unrelated events (i.e. events of different type and nature). Are multiple events experienced by children related or unrelated, and how does this effect the appraisal of such events? Brown & Harris (1978) considered four ways in which events might 'add': 'mechanical additivity', which may occur independently of the meaning of events, implying a threshold of stress above which psychiatric disorder is likely; 'general appraisal', where, although events are perceived as 'unrelated', the subject feels unable to cope with any further personal stressors; 'specific appraisal', where events have particular meaning and implications for the subject which indicates that one event may be related to another; and 'symbolic appraisal', where the first event influences the second through individual personal significance, unrelated to contextual information, but reflecting intrinsic psychological associations made by the subject. All four types of additivity can be usefully considered for childhood and adolescence.

The present results suggest that for conduct disorders events may exert a degree of mechanical additivity, as they exert effects independent of the nature of social context (Goodyer *et al*, 1985*a*). However, for the other three groups of mood and somatic presentations there seems likely to be a more qualitative appraisal. Whether this is general, specific, or symbolic for one or all of the groups cannot be clearly stated from the findings.

Finally, rapid effects occur independent of the number of events. This mechanism is not a function of additivity. Since the time period between event and onset of symptoms is short this may reflect a direct effect of an event on well-being; whether this is a result of qualities of the event, for example its severity, or of particular types of appraisal by certain children is unclear.

Perhaps certain types of children are more likely to respond with rapid effects to undesirable events. Factors which make them liable to do so may be intrinsic (temperament, organic factors) or extrinsic (family, social factors). Adverse experiences in the past or persisting as ongoing difficulties (Brown & Harris, 1978) may also contribute but were not examined in this study.

We hoped to provide some answers to four questions from this research. The first three have been addressed: events carry an increased risk of psychiatric disorder; they exert long-term, short-term, and rapid effects dependent to some extent on the number of events; and there is additivity of events in some cases, principally increasing the likelihood of a short-term effect.

The fourth question concerned the specificity between timing and number of events and type of disorder. Overall the proportions of cases reporting events is similar between the clinical groups, with a half to two-thirds of all cases experiencing one or more events. The distribution of events over time indicates little specificity between clinical group and type of effect (long-term, short-term or rapid).

The number of events for each clinical group shows that only conduct disorders have more multiple-event than single-event cases. We have previously shown that events carrying no or mild negative impact are associated with conduct disorder but no other group (Goodyer *et al*, 1985*a*). Since these mild events are not included in this analysis we may have underestimated the effects of multiple events for conduct disorder.

The small numbers in the clinical groups prevent firm statements about the specificity of timing and numbers of events. However, there is a suggestion that conduct disorders are the least likely to experience long-term effects and the most likely to experience multiple events. On the basis of the results this finding is what one might predict, as multiple events are more associated with short-term effects and we have already speculated that mechanical additivity of events may be more likely in conduct disorder.

The lack of specificity between timing and number of events and diagnosis may be a function of sample size, but may also be improved by further clarifying the nature of life events. For example, the findings of Finlay-Jones & Brown (1981) suggest that dangerous events are more associated with anxiety and loss events with depression.

A number of methodological issues require comment. Firstly, we previously indicated that there are likely to be advantages in obtaining life event data from children, particularly as the personal appraisal of stressors by children requires considerable further research (Goodyer *et al*, 1985*a*). Secondly, we cannot be sure that the effects exerted by life events on disorders are not simply a function of some other factor not accounted for in this research. Thus a spurious association between events and disorder, while unlikely in our opinion, may be present. Clearly the relative contribution of events to disorder requires examination. We have already indicated that some 30% of cases did not experience a recent severe life event and 17% of community subjects did. Thus recent events carrying a moderate to severe degree of negative impact may be sufficient in some instances but clearly not necessary in all for the development of psychiatric disorder in young people.

Although these methodological issues must be addressed in future studies the results presented here do indicate that recent stressful events exert different effects on emotional and behavioural disorders, according to their number and timing.

Appendix

'Relative risk' measures the association between a particular factor and risk of a certain outcome, and is the ratio of the rate of disease among those exposed to the rate among those not exposed. This measure of magnitude depends on a precise enumeration of the number of cases in the general population or sub-groups of it in order to estimate incidence rates in exposed and non-exposed populations. This presents difficulties in psychiatry, and it is not possible to estimate incidence rates in exposed and unexposed populations from a retrospective design. However, an approximation of relative risk can be made from a case control study using a 2 × 2 contingency table. The assumption made is that instead of representing cases and controls the entries reflect the true proportions of the population with and without the disease and with and without the cause. Calculation of relative risk from a 2 × 2 contingency table constructed from a case-control study can be made as follows:

Suspected cause	*Cases*	*Controls*
Present	A	B
Absent	C	D

Therefore:

Risk of disease in those with cause = $A/(A+B)$

Risk of disease in those without cause = $C/(C+D)$

Relative risk = $(A/(A+B))/(C/(C+D))$

If the proportion of the population affected by the disease is relatively small compared with those unaffected then:

$B \approx A+B$

$D \approx C+D$

and the formula reduces to AD/BC.

If the proportion of the population affected by the disease is relatively large, the ratio is a useful measure of disease risk between groups and is best termed 'relative odds', i.e. the ratio of affected to unaffected individuals is one divided by the same ratio in another group.

Prescribing Information ▼ **Presentation:** Round, yellow, enteric-coated tablets each
50mg fluvoxamine maleate, imprinted with 'Duphar 291'. Pack of 60 tablets, basic NHS price
ses: Treatment of those affective disorders characterised by persistent low mood, impaired
or activities and psychosomatic complaints. **Dosage and Administration:** The tablets should
ved without chewing and with water. Adults: The effective daily dose usually varies between
200mg and should be adjusted to the individual response of the patient up to a maximum of
e minimum recommended starting dose is 100mg given in the evening. A total daily dosage in
00mg should be given in divided doses. Elderly: The same dosage regimen may be utilised in the
n the general population. Children: There are insufficient data to recommend the use of Faverin in
ontra-indications, Warnings, etc: Faverin should not be given together with or within two
terminating treatment with monoamine-oxidase inhibitors. Patients with hepatic or renal
cy should begin treatment with a low dose and be carefully monitored. Faverin has no effect on
or skills associated with driving and operating machinery. However, in combination with alcohol
irment may be seen. Use in pregnancy and lactation: There has been little human use but there
o adverse animal evidence. Avoid in pregnancy and in nursing mothers if a better known and safer
is available, although safety in pregnancy is likely. Interactions with other drugs: In interaction
studies increased plasma levels of propranolol and warfarin were seen during concurrent admini
Faverin. Care should be taken when Faverin is prescribed to patients already receiving propra
warfarin as the dose of these drugs may need to be lowered. No interactions were seen with digo
atenolol. **Side-effects:** The commonest symptom observed with Faverin administration is nau
usually diminishes early during the course of treatment. Other treatment emergent symptoms
during clinical studies were somnolence, constipation, agitation, anorexia and tremor. Other report
are often associated with the illness and their incidence in controlled trials is comparabl
experienced with placebo. Faverin may cause a decrease in heart rate. During treatment, limited
repolarization were observed in the ECG, but no causal relationship could be demonstrated. The in
postural hypotension was similar to that seen in patients treated with placebo. Treatment of overd
specific antidote is known. The stomach should be emptied as soon as possible after tablet ing
symptomatic treatment should be given. The use of medicinal charcoal is also recommended.
Quantities 50mg tablets: available in packs of 60 (3 strips of 20 blister-packed tablets). **Product
Number** 50mg tablets: 0512/0070. Further information is available from: Duphar Laboratorie

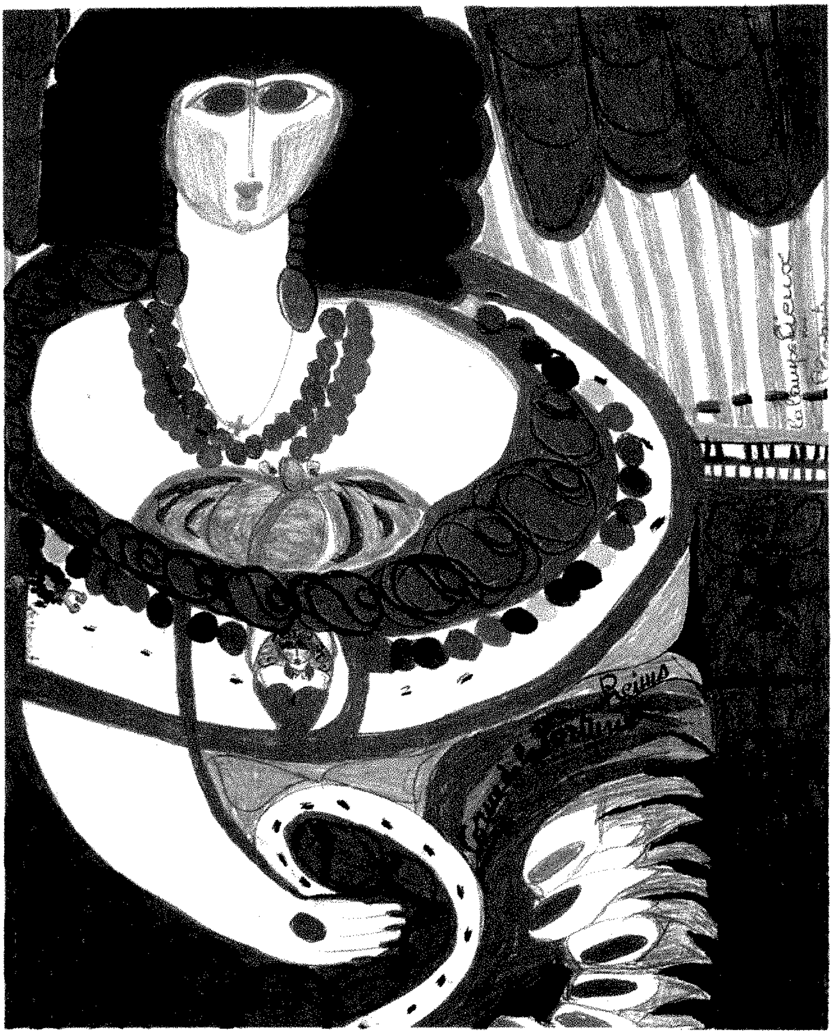
Highly Selective 5-HT Reuptake Inhibitor

AN EXPRESSION OF SCHIZOPHRENIA.

Aloise was diagnosed as schizophrenic at the Cery Asylum, Lausanne. She was later transferred to the Asylum de la Rosiere where she remained for over 40 years until her death in 1964.

During the last 20 years of her life she worked steadily at her drawings.

The illustration below is produced with kind permission of the Musee Cantonal Beaux-Arts, Lausanne.



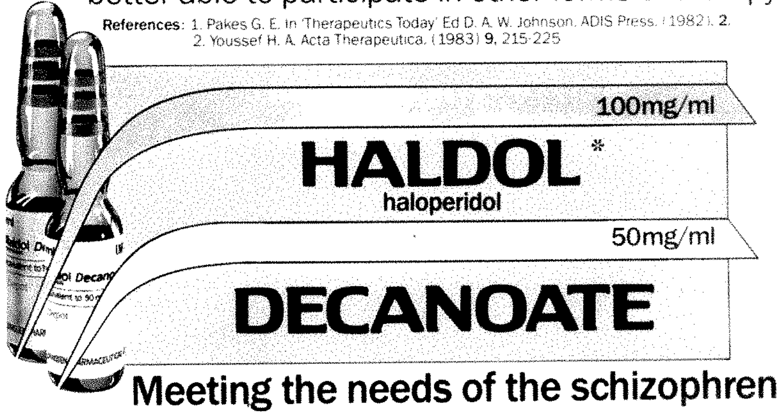
A TREATMENT.

Since the 1950s when Dr Paul Janssen and co-workers researched and developed the prototype butyrophenone haloperidol, it has become widely established throughout the world as an effective anti-psychotic. In 1982 Haldol* Decanoate was introduced to the UK as a depot neuroleptic with a consistent 4 week duration of action following a single deep intramuscular injection.

In mild symptomatology the dosage for Haldol* Decanoate is from 50-100mg given 4-weekly, whereas severe schizophrenic symptoms are usually controlled with up to 300mg.

The schizophrenic patient can benefit from a flexible therapy with little incidence of sedation[1] and a reduced requirement for antiparkinsonian medication,[2] leaving him/her better able to participate in other forms of therapy.

References: 1. Pakes G. E. in 'Therapeutics Today' Ed D. A. W. Johnson, ADIS Press. (1982). **2.**
2. Youssef H. A. Acta Therapeutica. (1983) **9**, 215-225



Meeting the needs of the schizophrenic.

Presentation: Straw coloured, viscous solution presented in 1ml brown glass ampoules equivalent to 100mg/ml haloperidol (as decanoate ester) and 1ml brown glass ampoules equivalent to 50mg/ml haloperidol (as decanoate ester) both in packs of 5. **Uses**: As a depot injectable form of haloperidol indicated for adults where long term maintenance treatment with a neuroleptic is required, for example in schizophrenia, other psychoses (especially paranoid) and other mental or behavioural problems where maintenance treatment is clearly indicated. **Side effects, precautions, contra-indications**: Haloperidol is not recommended during lactation. Use in Pregnancy: The safety of haloperidol in human pregnancy has not been established. Precautions: Caution in liver disease, Parkinson's disease, phaeochromocytoma, thyrotoxicosis, epilepsy and conditions predisposing to epilepsy. Antagonism of adrenaline, guanethidine, phenindione, anti-Parkinson effects of levodopa and impairment of metabolism of tricyclic anti-depressants have been reported. Haloperidol may increase the effects of CNS depressant drugs, and enhanced CNS effects when combined with methyldopa have been reported. Neurotoxic reactions to combined treatment with lithium and haloperidol have been reported. Side effects: In common with all neuroleptics, the following side effects may be observed, sedation, extra-pyramidal symptoms, tardive dyskinesia, mental dullness, dizziness, headache, excitement, agitation, insomnia, hyperprolactinaemia, galactorrhoea, gynaecomastia, oligo- or amenorrhoea, hypotension. Gastro-intestinal symptoms and weight changes have been reported. Anti-Parkinson agents should only be given as required. The elderly are more susceptible to sedative/hypotensive effects. Occasional local reactions such as erythema, swelling or tender lumps have been reported. In common with other anti psychotics, haloperidol has been associated with rare cases of neuroleptic malignant syndrome. **Dosage**: Haldol* Decanoate provides one month's therapy following a single deep intra-muscular injection in the gluteal region. An initial dose of 50mg every 4 weeks is recommended increasing if necessary after 2 weeks by 50mg increments to 300mg every 4 weeks. The dosage should be tailored to suit the individual patient and to reflect previous oral dosage. In adults 100mg Haldol* Decanoate is approximately equal to 500mg chlorpromazine (or equivalent) per day. Caution is required with the elderly, starting doses of 12.5mg to 50mg monthly should be tried first. **Product Licence Numbers**: 0242/0095, 0242/0094 **Basic NHS Cost**: 1ml x 100mg/ml x 5 £24.00 1ml x 50mg/ml x 5 £15.60. (Correct at time of printing). Further information is available on request from: **Janssen Pharmaceutical Limited**, Grove, Wantage, Oxon OX12 0DQ.

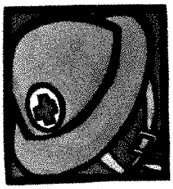
JANSSEN
PHARMACEUTICAL LTD

So what has Lilly ever done for Britain?



Well, where should we start?

The Second World War seems as good a place as any. By 1942 around one third of the production capacity of our newly-built Basingstoke factory was devoted to producing medicines for Britain's armed forces.

From foot powders to burn treatment, products manufactured by Lilly played their part in Britain's war effort.

Today we are contributing more than ever to Britain.

Our Part in Building Basingstoke

In 1939 we opened our first manufacturing plant in Britain, at Basingstoke. In those days the town had a population of less than 20,000. Today it is a busy commercial centre of 90,000 people.

As one of Basingstoke's biggest and longest established employers, we are proud of our role in the town's growth and current success.

Just the Job for Liverpool

At Speke on Merseyside, our antibiotics processing plant provides much needed jobs for 900.

In fact, our Speke General Manager was recently awarded an OBE for his 'outstanding contribution to alleviating the problems of Merseyside.'

Add in our other UK operations, including our research centre in Surrey, and Lilly Industries Limited employs over 2,000 people throughout Britain.

The Health of the Nation

Leaving aside our contribution to the economy's well-being, we also do a considerable amount for the nation's health.

As one of the world's leading pharmaceutical companies, we have discovered and developed numerous important drugs.

An Indispensable Discovery from Lilly

It was Lilly who pioneered the Vinca Alkaloid group of compounds. These are widely used in Britain in the treatment of childhood leukaemia and are described by the Oxford Textbook of Medicine as 'indispensable.'

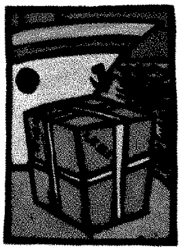
Thanks in part to this discovery, a condition that once almost always condemned young sufferers to death now has a vastly improved prognosis.

Then there was our work in the development of oral antibiotics. Before their introduction, administering antibiotics was a laborious and costly process. Expensive for the NHS and painful for the patient. With our help, the discomfort of both parties has been considerably lessened.

More recently, in 1982, we introduced genetically engineered human insulin manufactured in our plant in Speke. The benefit to patients with diabetes in Britain and around the world is unquestionable.

Where Research Becomes Reality

The success of our products is based, to a great extent, on research. UK research personnel located at our Erl Wood Research Centre in Surrey have contributed greatly to many of our worldwide projects, a prime example of Britain's expertise in the pharmaceutical field.



Exporting to the World

Lilly Industries Limited ranks among Britain's top exporters. Products manufactured here are distributed around the world, netting millions for Britain's balance of payments each year.

And what of profits? As an American company, do all the financial benefits wing their way back across the Atlantic? Not at all.

Investing in Britain

Our investment in Britain now tops over $140 million. In the last five years alone we have ploughed back $80 million. What is more, with our continued commitment to innovative pharmaceutical fields such as rDNA technology, we'll be spending a lot more in Britain in the next few years.

Employment, economic growth, investment and expertise. Just a few of the things an American pharmaceutical company has done for Britain.

Brief Psychotherapy in the Treatment of Anorexia Nervosa
Outcome at One Year

A. HALL and A. H. CRISP

Thirty out-patients with severe anorexia nervosa were randomly allocated to either 12 sessions of dietary advice or 12 sessions of combined individual and family psychotherapy. At one-year follow-up both groups showed significant overall improvement, and the dietary advice group showed significant weight gain. A similar mean weight gain for the psychotherapy patients did not reach statistical significance, but this group made significant improvements in sexual and social adjustment.

The long-term outcome of anorexia nervosa (AN) has been reviewed by Hsu (1980). Although outcome at one year bears some relationship to that at four years (Morgan & Russell, 1975; Hsu *et al*, 1979), longer-term studies (Theander, 1983) confirm the view that AN is often a relapsing remitting condition over many years, and that short-term restoration of body weight may have little bearing on future psychosocial functioning. In an attempt to reduce the relapse rate, psychotherapy in various forms has been incorporated into most treatment programmes.

While impressive results have been reported for family therapy (Palazzoli, 1978; Minuchin *et al*, 1978), there is little evidence that this short-term improvement is maintained in the longer term, and there have been no reports of prospective treatment studies evaluating the effectiveness of psychotherapeutic approaches (Garfinkel & Garner, 1982). The specific methodological difficulties of randomly allocating AN patients to different psychotherapeutic treatment modalities within one centre have been described by Szmukler (1983); those general to and inherent in all psychotherapy research have been discussed frequently (Bergin & Strupp, 1972; Luborsky *et al*, 1975; Sloane *et al*, 1975; Malan, 1976; Schlesinger *et al*, 1980; Conte & Karasu, 1981; Brodaty & Andrews, 1983). The dictates of study design and therapist variables in particular may interfere with delivery of a treatment which by its nature must be intuitive, flexible, and tailor-made for the needs of the patient. Frank (1971) identified the therapeutic factors in any patient-therapist relationship, and Strupp & Hadley (1979) attempted to investigate the relative contribution of the therapist's technical skills and of non-specific interpersonal components. DiMascio *et al* (1979) discussed the problems of a control group, and concluded that a non-scheduled treatment group had both ethical and scientific advantages for acutely depressed patients over waiting-list, assessment only, low or minimum contact, or untreated control groups. A controlled psychotherapeutic treatment study for patients with bulimia nervosa has been described by Lacey (1983): a mixture of individual behaviourally orientated therapy and group therapy produced improvement, as compared with no treatment, after initial assessment.

Since AN bears a significant mortality and morbidity, difficult ethical issues must be considered in any research design, but while specialist treatment resources remain scarce and no approach has proved definitively superior, limited treatment trials are justified, although studies with untreated controls probably are not. Morgan & Russell (1975), Crisp *et al* (1977), and Hsu *et al* (1979) have identified factors associated with a worse prognosis, which must be taken into account in any controlled study and in comparing results. Since the number of treatment variables should be kept to a minimum, an out-patient study is more feasible than an in-patient one, overcoming the problems of psychotherapeutic contact with other staff and the difficulties of maintaining blind treatment allocation. This approach seems justified by the findings of the St George's Hospital series (Hsu *et al*, 1979): 71% of the subjects treated with out-patient psychotherapy had good outcomes, compared with 41% after in-patient care. However, although the authors did not attempt to distinguish between the two groups in terms of factors predictive of poor outcome, the in-patient group, who received more intensive individual and family psychotherapy, were almost certainly more chronic and severely ill patients.

The aim of the present study was to investigate the effect on weight, eating behaviour, and social and sexual adjustment of either brief individual and family psychotherapy or dietetic advice for out-patients with AN. The clinical findings at one year follow-up are described.

Method

Subjects

Thirty female subjects who met the diagnostic criteria for primary AN were selected from consecutive referrals to one of the authors. To control for some of the factors found to affect prognosis in previous follow-up studies (Morgan & Russell, 1975; Crisp *et al*, 1977; Hsu *et al*, 1979) the subjects selected were aged 13–27, from social classes I–III (Registrar General's classification, Office of Population Censuses and Surveys, 1985), and unmarried. They all weighed less than 85% of matched population mean weight (MPMW), had amenorrhoea, and had been ill for between 6 and 72 months.

The referring agent–in most cases the subject's general practitioner–was informed that out-patient treatment in the form of either brief psychotherapy or dietetic advice would be offered, and was advised to seek additional treatment elsewhere should this be insufficient to prevent serious deterioration during the period of the study. However, if admission or further treatment were indicated at the one year follow-up appointment it would be made available within the department.

Referrals were screened initially by postal questionnaire, and those meeting the criteria for inclusion were invited, together with their families, for a two-hour assessment interview. Each subject and her family were interviewed by a psychiatrist and a dietitian, to record full clinical and demographic details, including weight, desired body weight, eating pattern, history of AN, past and current relationships with family, and psychosexual history. The clinical and family dynamic assessment took the form outlined elsewhere (Crisp, 1980): it included evaluation of the subject's personality, mental state, family dynamics, and motivation for treatment which had the goal of increasing insight, including psychological change in both the subject and family. Each subject completed a Crown-Crisp Experiential Index (CCEI) (Crown & Crisp, 1979) and scores were calculated for body weight, menstrual function, eating pattern, mental state, and sexual and social adjustment (Morgan & Russell, 1975; Hsu *et al*, 1979). The global clinical score for each subject was the mean of these six scores.

All subjects who met the criteria for inclusion in the study were willing to attend for out-patient treatment and, following assessment, were randomly allocated to treatment with either the psychotherapist or the dietician.

Psychotherapy group

Fifteen subjects were each seen for 12 sessions of one hour's duration at one to two-weekly intervals, by the same psychotherapist. The proportions of individual psychodynamic therapy and family therapy depended on clinical judgement, practicability, and the willingness of the family to be involved. The therapist was trained and experienced in these therapeutic approaches, and in the flexible integration of family and individual work as appropriate. In each case attention was focused on the role AN played in the relationship of the subject with her family and others. An attempt was made to change those aspects of relationships which tended to stifle the subject's development and maintain the anorexia, particularly over-protectiveness, conflict avoidance, enmeshment, and distancing within the family. The specific goals of treatment varied in each case, particularly depending on the age of the patient, but were broadly to encourage her development, both within and separately from her family, and to promote insight. All patients were seen by the dietitian for four 15-minute interviews during the course of treatment, during which they were weighed, their general progress (particularly regarding eating behaviour) discussed, and dietary advice given.

Dietary advice group

Fifteen subjects were seen for twelve one-hour sessions at weekly or fortnightly intervals. Five dietitians were involved; each treated the subjects she had assessed, and all were experienced in the dietary management of AN. Each session was spent discussing diet, mood, and daily behaviour patterns. The family was seen with the subject on some occasions. The goals of treatment were to restore normal eating patterns and dietary constituents, to relate eating behaviour to mood, and to increase the confidence of the subject so that she could remain in control as she gained weight. All subjects were seen by the psychotherapist for four 15-minute interviews, during which they were weighed, then general progress discussed, and advice given, particularly about family and social relationships.

At the end of treatment all 30 subjects again completed the CCEI, and their general practitioners were contacted.

Follow-up

One year after the assessment interview, all the subjects and their families were interviewed by an assessor who was blind to the treatment allocated. The clinical and demographic details recorded initially were reviewed, and the CCEI repeated. Sexual and social adjustment scores were calculated, and the mean of these, body weight, food intake, menstrual function, and mental state scores was calculated to give the global clinical score. Details were taken of treatment received elsewhere and of other life changes in the subjects or families since the last contact with the department. The assessor reviewed each subject's progress in terms of her AN, and her overall development, both social and sexual, as an individual and within the family. Whenever indicated, recommendations for further treatment were made. If the patient and her family did not accept the offer of further treatment, alternative follow-up was offered.

Results

Characteristics at initial assessment

The clinical features at presentation are summarised in Table I. There were no statistical differences between the

2. Two of this group never menstruated.

two groups on any of these variables, or on individual CCEI scales. The clinical features and CCEI profiles resembled those of other studies (Morgan & Russell, 1975; Crisp *et al*, 1978, 1980).

Treatment compliance

Fourteen of the psychotherapy group (PG) patients completed 12 sessions of psychotherapy. One subject dropped out after six sessions, by which time her weight was within 8% of her MPMW and her menstruation had resumed; her improvement was sustained at follow-up.

Eleven of the dietary advice group (DAG) patients completed treatment. One subject gained 4 kg after the assessment interview, and refused further treatment; at follow-up she had gained more weight, but still had AN. Three subjects attended for three, seven, and nine sessions respectively; two of these gained weight during the period of treatment only and then remained static until follow-up, while the third lost weight during treatment, but had gained 10 kg by follow-up without resumption of her menses. During the period of the study she sought, and obtained, intensive treatment by a hypnotherapist. Another patient in this group was treated by an acupuncturist.

Body weight

Figure 1 shows the mean change in weight, expressed as percentage deviation below MPMW, for each group after 12 sessions of treatment and at follow-up. There was no

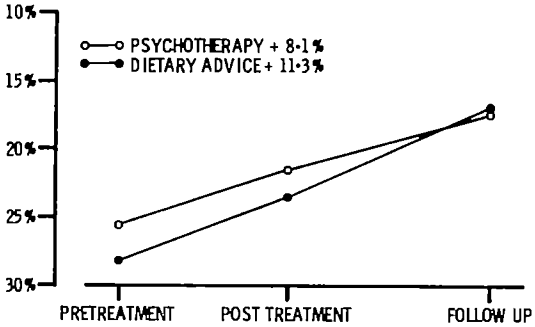

FIG. 1 Percentage deviation below matched population mean weight

statistical difference between the two groups, both of which showed a similar overall gain. This gain was significantly different ($P < 0.001$) from the presentation weight for the dietary advice group only; the PG patients made similar gains, but three showed major weight losses (mean 9.0 kg) after treatment ended, which to some extent masked major gains (mean 10.4 kg) made by eight others, and resulted in a large standard deviation (8.04 kg) in weight at follow-up. In contrast, the DAG patients, with a standard deviation of 6.07 at follow-up, had sustained their gain since treatment, resulting in a significant mean weight gain overall.

Clinical features

The clinical features at one year are shown in Table II.

There were no significant differences between the two groups on any of the individual measures, except in the social ($P < 0.005$) and sexual ($P < 0.10$) adjustment scores, which were significantly higher for the PG. The PG showed a significant improvement in social adjustment ($P < 0.001$) and in sexual adjustment scores ($P < 0.001$) between presentation and follow-up, while the DAG showed slight non-significant improvement. Both groups showed significant improvement ($P < 0.001$ for PG; $P < 0.01$ for DAG) in global scores after one year (Fig. 2).

Changes following treatment

The two groups differed in the treatment received elsewhere during the study. None of the PG sought outside treatment, but one patient, who had made progress, deteriorated seriously as soon as treatment ended, and was admitted for 91 days to a medical ward for intravenous feeding, while another was seen as a medical out-patient for diarrhoea contracted during foreign travel. In the DAG, one patient attended an acupuncturist and another a hypnotherapist. After treatment with the dietitian ended, a further four patients attended 68 out-patients appointments for AN. Another patient in the same group, despite gaining weight with resumption of menses, was admitted to a psychiatric hospital for 126 days and attended a day hospital for 78 days; she made seven suicide attempts. Another patient was admitted for 123 days for treatment of her AN.

Nine of the PG patients visited their general practitioner for an average of two visits each after treatment ended, while nine of the DAG who did not receive other treatment made a total between them of 32 visits. Three received medication continuously and one briefly prior to follow-up, while four psychotherapy patients were prescribed medication for a short time.

During the year of the study three of the PG left home and ten acquired boyfriends, compared with one and three respectively of the DAG. The difference in respect of the boyfriends is significant ($\chi^2 = 6.65$, d.f. = 1, $P < 0.01$).

At follow-up, the parents of one subject in each group had separated. The assessor considered that there had been significant family realignment in the families of 12 of the PG subjects, compared with four of the DAG.

Both groups showed marked improvement at follow-up in eating behaviour. The reduction in the symptoms of food avoidance and anxiety about eating with other people was more marked in the PG, while the DAG tended to show a greater improvement in bulimia, vomiting, and purgation. The symptom of 'weight phobia' improved, and was reflected in the desired body weight, which increased by 7 kg for the PG and by 3.5 kg for the DAG (Table II).

Seven of the PG and five of the DAG had resumed menstruation at one year.

CCEI changes

There were no significant differences in CCEI scores between the two treatment groups. The DAG showed significant decreases in the somatic ($P < 0.005$), phobic ($P < 0.025$) and depression ($P < 0.05$) scales (Fig. 3), whereas the PG showed significant ($P < 0.05$) but small falls in the obsessional and depression scores (Fig. 4). One patient, who had deteriorated clinically, refused to complete her CCEI at follow-up.

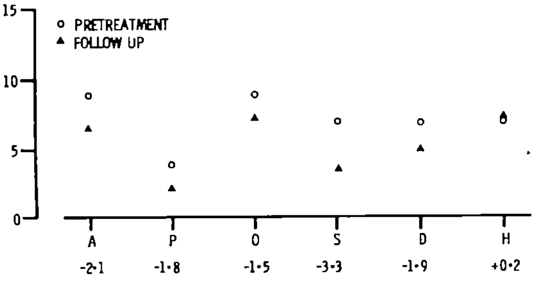

FIG. 3 Mean CCEI scores for the dietary advice group ($n = 14$). The scales are designated as follows: A = anxiety; P = phobic; O = obsessional; S = somatic; D = depressive; and H = hysteria

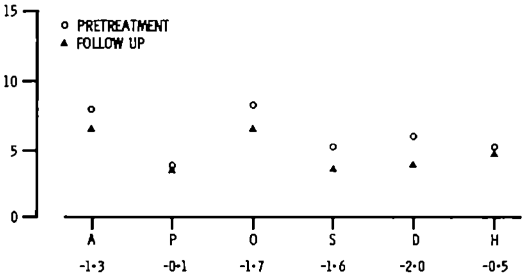

FIG. 4 Mean CCEI score for the psychotherapy group ($n = 15$)

Treatment recommendations

At follow-up, four of the PG were considered recovered and did not require further treatment; all 11 remaining patients accepted and attended the recommended further psychotherapy or infrequent follow-up appointments. All 15 of the DAG were felt to require further treatment but only ten accepted the offer, and two of these dropped out almost immediately. The independent assessor detected a greater degree of motivation to overcome anorexia on the part of the PG; he noted that some of the DAG were reluctantly co-operative in their acceptance of treatment.

Discussion

It has been suggested that it is simplistic to focus on weight gain and return of menstruation alone as indicators of improvement in AN, and that intrapsychic and interpersonal conflicts, sexual and social adjustment, and continuing development are at least as important (Bruch, 1974; Crisp, 1980; Garfinkel & Garner, 1982). This study demonstrates that significant improvement in overall functioning, as reflected in the global clinical scores, may have been achieved by two different brief interventions: dietary advice, or a mixture of individual and family therapy.

On individual measures both groups show modest improvement in weight, menstruation, eating patterns, and sexual and social adjustment after one year, but differ significantly in outcome on three measures. The DAG showed significant weight gain, whereas the PG made significant improvements in sexual and social adjustment. When the patterns of change in weight for each patient are examined more closely, the two groups show distinct differences. The DAG had a more uniform pattern during treatment of modest gains in weight, which tended to be sustained between the end of treatment and follow-up; these patients were more likely to seek alternative treatment elsewhere during the treatment period and afterwards, which may have sustained them. In contrast, the PG was characterised by larger weight gains during treatment, but the subjects tended either to continue to improve, or to relapse–in three cases seriously–during the period in which there was no contact with them.

The changes in CCEI scores, which on some scales reached statistical significance at follow-up, showed trends supporting these findings, and may be related to aspects of the psychotherapeutic process. The PG patients tended to have higher anxiety and depression scores after the 12 treatment sessions, whereas the other group showed a small increase in the obsessional scale; both groups showed lower mean scores overall at one year. Crisp *et al* (1979) have shown that increased anxiety and depression during treatment are associated with improved long-term prognosis, and may indicate a reduction of the denial characteristic in AN. The CCEI changes are difficult to interpret, but might reflect intrapsychic changes and emotional awareness provoked by psychotherapy, whereas dietary advice may reinforce denial, obsessional defences, and control–in some cases stabilising the course of the illness. This provides an explanation for the deterioration of some PG patients when the 12 sessions of treatment ended, and illustrates a major drawback of rigid treatment design in psychotherapy research.

The general problems of study design in psychotherapy research are present in this study. Firstly, patients subsequently allocated to 'dietary advice' nevertheless also receive, together with their families, an initial extensive diagnostic evaluation and related discussion. Crisp (1980) and Malan *et al* (1975) have emphasised the occasional important psychotherapeutic effect of such interventions. Secondly, neither treatment approach can be 'pure'; inevitably, the dietitians discussed family and other issues raised in their sessions, while the psychotherapist at times focused on eating patterns and other matters relating to diet. Treatment of the dietary advice group was additionally complicated by other treatments received simultaneously by two of the patients. A further five patients were treated later in other psychiatric departments. We can assume, therefore, that up to half of the DAG may have received some psychotherapeutic treatment prior to follow-up: all of these had gained some weight between assessment and follow-up, but none had received family therapy or intensive psychotherapy. The contribution of these other treatments needs to be considered. Finally, the independent assessor could not always remain totally blind to the treatment received.

The one-year follow-up period is too short to make any long-term predictions, particularly as the majority of the patients required further follow-up or treatment–either admission to hospital or out-patient individual and family psychotherapy. The greater persistence of the PG in pursuing treatment, both at the outset and after follow-up, is clear.

Although the follow-up period was relatively short, the study supports the findings of others that many patients, even with long-standing AN, show improvement in physical and psychological functioning after a short period of intensive treatment of one kind or another, and that admission to hospital may not be necessary. The differences between the two groups highlight the changes which occur as a result of distinct elements of treatment, which are widely accepted but generally combined in most treatment centres. Our results emphasise that attention to both eating behaviour and psychological change are important in the treatment of AN, but offer a warning about the need for long-term continuity of treatment in some cases, particularly when intrapsychic or interpersonal changes are taking place.

Anorexia Nervosa: An Object Relations Approach to Primary Treatment

M. HORNE and M. GALLEN

Concurrent behaviour therapy and psychotherapy in the treatment of anorexia nervosa creates significant problems in the development of a therapeutic alliance and in the multiple roles staff are required to assume. Our protocol was developed to keep treatment personnel in their usual roles so that their various treatment skills could be fully utilised. A physician treated the anorexia with naso-gastric feeding, freeing the psychotherapist to act in the usual manner. This avoided role confusion, and the split of 'bad' and 'good' treatment personnel was appropriate and therapeutic, rather than pathological. Four successful cases are described.

Anorexia nervosa (AN) can cause severe cachexia, which can be extremely difficult to treat. A variety of techniques have been used to initiate weight gain, but long-term changes require psychotherapy (Bruch, 1974; Whipple & Manning, 1978). In addition to the physiological effects of cachexia and the ultimate risk of death there are pronounced cognitive and emotional changes which interfere with effective psychotherapy (Fox, 1981). Rapid and effective weight gain is important both for physical and psychological well-being.

Behaviour therapy is currently a fashionable method to induce weight gain. Our own experience with this method has been disappointing, firstly because weight gain is slow, inconsistent, and non-durable, and secondly because the most common behavioural treatment makes the consequence of the failure to gain weight the deprivation of ward privileges, and rewards weight gain by the granting of ward privileges (Agras & Werne, 1978). In this situation the reward is a reintroduction of the *status quo*, and not really a positive reinforcement. Deprivation of ward privileges is therefore the aversive consequence of a failure to gain weight. This aversive consequence is dependent on the outcome (i.e. weight gain) of a series of types of behaviour rather than a direct consequence of a type of behaviour itself as in the usual operant paradigm. The paradigm is therefore not really aversive operant conditioning – it is simply punishment for not gaining weight. The struggle for behavioural control between the mother and the patient is repeated between the therapist and the patient, without the scientific underpinning of a correct operant paradigm.

A working therapeutic alliance is difficult to create with anorexic patients because of their primitive object relations development (Sours, 1980; Masterson, 1977). Using behavioural therapy in conjunction with psychotherapy makes the therapist a bad object in connection with the former and a good one in connection with the latter, inhibiting the development of a working alliance. In addition there is role confusion among staff, as they are required to be both behaviourists and psychotherapists simultaneously. These patients use primitive defences such as projective identification and splitting; this creates additional chaos, as staff already confused in their roles become further split into good and bad objects (Cohen, 1978). On the comprehensive medical unit at Stanford Hospital we developed our treatment programme to avoid these difficulties.

Physicians are required to diagnose and treat physical illness; they work in a well-defined and socially sanctioned paradigm. We reasoned that since the cachexia caused by AN is a severe physical illness we should define it as such and ask the physician to treat the cachexia within the normal medical paradigm. The physician is then in his normal role, and the anorexic patient in this context assumes the role of a physically ill patient. The treatment for bowel disorders where nutrients are not being absorbed is some form of dietary supplementation, or parenteral feeding, depending on the condition. The logical treatment for anorexia is therefore naso-gastric tube feeding. The complications of naso-gastric feeding with a fine bore naso-gastric tube, constant infusion and careful metabolic monitoring are minimal, and far outweigh the dangers of cachexia (Silk, 1984).

In conjunction with the tube feeding, a psychiatrist and psychologist work collaboratively using an administrative therapy model. The psychiatrist deals with administrative, management and psychopharmacological issues, while the psychologist begins his or her work with the patient in the usual psychotherapeutic manner, free from any need to step out of his or her role.

The 'prescribed' splitting which occurs aids therapy, as the phyician and psychiatrist automatically become the bad objects and the therapist the good object, helping the formation of the therapeutic alliance.

We describe the treatment of four typical cases of AN using this method.

Method

The four female patients in this study had an unequivocal DSM-III diagnosis of anorexia nervosa (American Psychiatric Association, 1980). Their ages and weights (as a percentage of ideal body weight are given in Table I. All had begun to show features of the illness as teenagers. Three of the patients were admitted to the psychosomatic ward of Stanford University Hospital and one was admitted to a general medical ward. Two of them were already in psychotherapy and two had just presented for treatment. All patients were resistent to starting tube feeding, but were co-operative once the procedure was begun. The procedure was voluntary in all cases.

A paediatric naso-gastric tube was passed and remained in situ throughout the hospital stay. A nutritionally complete enteral formula (1 kcal/ml) was infused at a rate dependent on the presence of upper gastro-intestinal discomfort or loose bowel motions. A weight gain of 0.1–0.2 kg/day was maintained.

The physician co-ordinated all aspects of the medical management; the psychiatrist determined all aspects of case administration and management, and the psychologist saw the patient for daily psychotherapy. All patients had concurrent family therapy with a separate therapist, and the three patients who were married had some marital therapy.

Results

Weight gains, length of hospital stays and follow-up periods are given in Table I. At follow-up, three patients had successfully terminated therapy, and all had maintained their weight gains. They felt considerable anxiety when the procedure began, and then relief when they realised that they did not have to control their food intake. As treatment progressed, all patients began to eat in addition to the tube feeding. When body changes began to occur the patients became anxious again, but also more affectively responsive, and all therapy situations became more active and intense. This was especially noticeable in family and marital therapy. There were some attempts to split the physician and psychotherapist in relation to bargaining about rapidity of weight gain and the endpoint to treatment. However, all these issues were decided by the physician in relation to the patient's medical condition. Cognitive and general physical abilities improved throughout treatment.

TABLE I
Details of four patients treated by the method described

Variable	*Patient* 1	2	3	4
Age at admission: years	21	18	32	27
Percentage of ideal body weight at admission	74	67	70	71
Increase in weight during treatment: kg	6.6	5.5	7.8	5.5
Length of hospital stay: days	31	24	15	11
Length of follow-up: months	19	3	25	19

Discussion

These four cases demonstrate the effectiveness of this method in instituting rapid weight gain; in addition, the intensity and relevance of therapy were enhanced and the detrimental effects of pathological splitting reduced. All four patients showed such a similar pattern of response: this was characterised by initial anxiety, then relief, then fear, as body changes began, and then more intensity and relevance in the therapeutic work. It was as though the defence had been taken away and the inner conflicts had been laid bare, but in a context where there was adequate therapeutic support to deal with them. This effect was noted by Maloney & Farrell (1980) in their study using hyperalimentation. After conquering the initial fears that tube feeding would take away control of weight gain, patients were relieved that they did not have to engage in the daily struggle with food.

In all cases, the issues revealed in hospital required considerable further therapeutic work, but they could no longer be denied. This was especially important in regard to interpersonal issues; eating behaviour could no longer be the primary issue in the marriage or family. The psychotherapist continued to work with the psychological meaning of the disturbed eating behaviour to the patient. However, we reduced the patient's denial of the medical consequences of cachexia by confronting this as a serious medical issue. By assuming control of the patient's nutrition the physician started a struggle for control of the patient's health which was initially external, but with the ultimate goal of making this internal. We did not expect the patient to return to normal weight; only to stay out of medical danger. We set the threshold weight at 43 kg. The ultimate return to normal eating behaviour involved long and painstaking psychotherapeutic work.

It could be said that the essential element of an object relations paradigm had been satisfied by splitting the weight gain method from psychotherapy; therefore, why not use other methods to induce weight gain? We rejected behaviour therapy, as currently practised, on the theoretical grounds outlined previously. In addition, Agras & Kraemer (1984), in a summary of behaviour therapy studies compared with non-behavioural studies, have shown that behavioural methods are only slightly superior.

In one of the few studies designed to establish the variables responsible for weight gain (Agras *et al*, 1974) it was shown that positive reinforcement (reinstatement of ward privileges) only induced weight gain if accompanied by feedback as to the calories eaten, mouthfuls eaten and weight gained. Patients realised that it was safe to gain a small amount of weight, and therefore gave up control to the therapist and allowed this to happen. This was an important element of our method. Patients were aware of the flow rate and concentration of the material infused. The physician adjusted this to keep weight gain between 0.1 and 0.2 kg/day. Patients would eat as desired, and ate more or less depending on how anxious they felt about weight gain – especially when body changes were occuring. The physician consistently maintained the steady weight gain, with the rationale that health needed to be restored but that the patient's fears would be respected and that some element of control (i.e. the fixed rate of weight gain) would be given to the patient. The feedback created a feeling of safety and added to the patient's trust in her physician. Our paradigm therefore used an essential element of the behavioural method in a more direct and theoretically accurate manner. In essence we provided the 'good-enough parenting' described by Winnicott (1965), making sure that health was restored to reasonable levels so that the struggle with good and bad objects could safely and therapeutically occur.

An important point was that weight maintenance at a safe level was now linked to medical necessity. It could be said that tube feeding would encourage patients to deny responsibility for their behaviour. However, this is an essential element of the illess: all anorexic patients deny the serious consequences of their eating behaviour. Our method focuses serious medical attention on the consequences of the denial, while attempting to undo the denial by psychotherapy.

Nursing and general ward management of these patients was vastly improved compared with previous experiences. The staff had much greater freedom to manage the therapeutic relationship normally, without the need to intrude in a non-neutral manner. The method is cost effective, enhances psychotherapy progress, improves milieu management, and allows safe weight gain.

CLOPIXOL TABLETS contain zuclopenthixol dihydrochloride.
Indications Psychoses
Dosage and Administration The usual initial dose is 20-30mg/day, increasing as necessary to a maximum of 150mg/day, in divided doses. The usual maintenance dose in chronic schizophrenia is 20-50mg/day in divided doses. Not recommended for children.
Side-effects Extrapyramidal side-effects may occur and sometimes may require control by anti-Parkinson drugs
Contraindications Acute alcohol, barbiturate or opiate poisoning. Intolerance to other neuroleptics. Pregnancy (relative). Use with caution in patients with Parkinsonism, severe arteriosclerosis, senile confusional states; serious renal, hepatic or cardiovascular disease
Overdosage Overdosage should be treated by gastric lavage.

Package Quantities and NHS Price (correct at time of printing) Bottles of 100 Clopixol Tablets 2mg £3.05, bottles of 100 Clopixol Tablets 10mg £7.50, bottles of 100 Clopixol Tablets 25mg £15 60
PL Nos 0458/0027,0028,0029. PA Nos 115/5/3,4,6

CLOPIXOL INJECTION & CLOPIXOL CONC. INJECTION contain zuclopenthixol decanoate 200mg/ml and 500mg/ml respectively in thin vegetable oil
Indications Psychoses, especially schizophrenia
Dosage and Administration 200-500mg every 2-4 weeks by deep intramuscular injection.
Not recommended for children.
Side-effects Early (frequent) and late (rare) dyskinesias. Extrapyramidal effects sometimes require dose reduction or anti-Parkinson treatment
Contraindications Comatose states.

Precautions Caution in patients with advanced renal, hepatic, or cardiovascular disease, Parkinson's disease, pregnancy, car driving or machine operation
Further Information Overdosage should be treated by (a) anticholinergic anti-Parkinson drugs if extrapyramidal symptoms occur. (b) By sedation (with benzodiazepines) in the unlikely event of agitation or excitement. (c) By noradrenaline in saline intravenous drip if the patient is shocked
Package Quantities & NHS Price (correct at time of printing) 10 x 200mg (1ml) ampoules £30.14, 1 x 200mg (10ml) vial £28 63, 5 x 500mg (1ml) ampoules £36.23

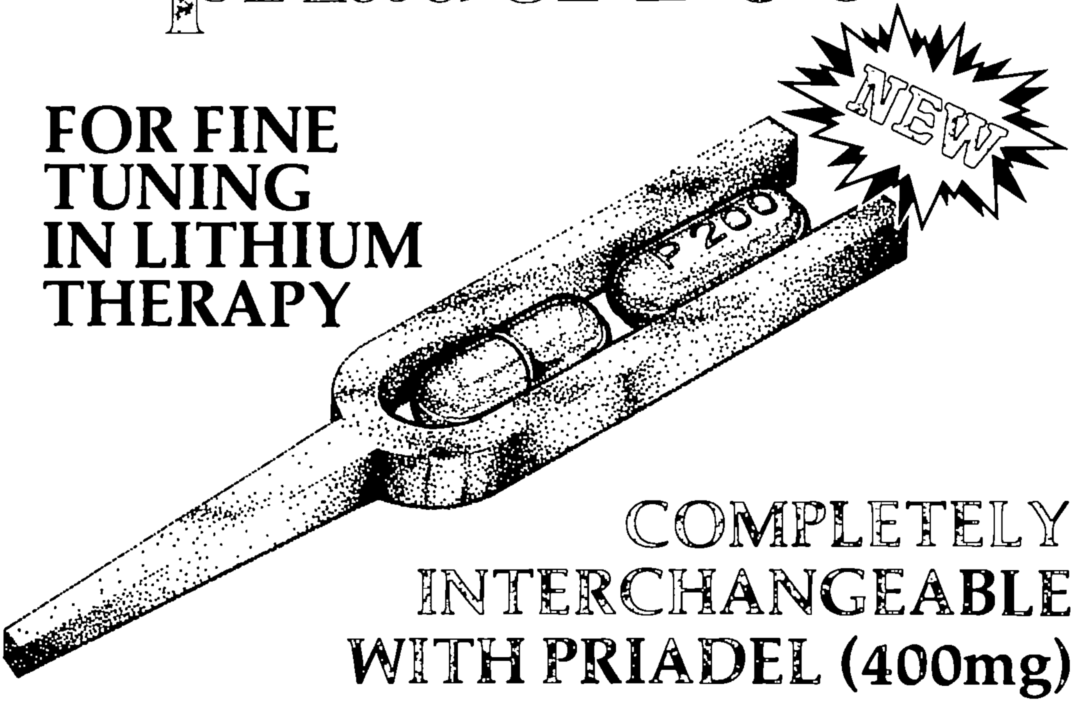
priadel® 200

FOR FINE TUNING IN LITHIUM THERAPY



COMPLETELY INTERCHANGEABLE WITH PRIADEL (400mg) WITHOUT RE-STABILISATION

priadel® — the world's first controlled release lithium now offers maximum flexibility of dosage

---

PRESCRIBING INFORMATION

Presentation
Each Priadel 200 Tablet contains 200mg lithium carbonate Ph.Eur. in a controlled release formulation. Also Priadel Tablets each containing 400mg lithium carbonate in the same controlled release formulation.

Indications
Treatment and prophylaxis of all elements of affective illness. For the control of aggressive or self-mutilating behaviour.

Dosage
In patients of average weight (70kg) 400—1200mg daily as a single dose, usually on retiring. Check serum lithium level at least 12 hours after the last dose on day 4 or 5. The twelve-hour serum level should be in the range 0.7—1.0 mmol/l. Adjust dose where necessary and check serum lithium level weekly until stabilisation has been achieved.

Contra-indications, warnings etc.
Renal and cardiovascular insufficiency. Addison's disease and untreated hypothyroidism. Recommendation to discontinue Priadel before planned pregnancy and for the first trimester. Exercise care in circumstances where electrolyte balance may be disturbed due to concurrent infections or other medication, for example diuretics, appetite suppressants and steroids. See Data Sheet for reported possible drug interactions.

Side effects and precautions
Initiation of lithium therapy may give rise to transient side effects which usually disappear following stabilisation. These include fine hand tremor, weight gain, polydipsia, polyuria and anorexia. Nausea and diarrhoea which are related to the site and rate of absorption are minimised by the controlled release formulation of Priadel. Long-term treatment with lithium may be associated with disturbances of thyroid or renal function which should be monitored.

Toxic effects which may be indicative of impending lithium intoxication include: increasing anorexia, diarrhoea, vomiting, muscle weakness, lack of co-ordination, drowsiness or lethargy progressing to giddiness with ataxia, tinnitus, blurred vision, dysarthria, seizures and coma.

Hereditary Agoraphobia and Obsessive-Compulsive Behaviour in Relatives of Patients with Gilles de la Tourette's Syndrome

D. E. COMINGS and B. G. COMINGS

We present 11 pedigrees in which a propositus with Gilles de la Tourette's syndrome had first or second-degree relatives with obsessive-compulsive behaviour or agoraphobia with panic attacks, but only partially expressed the TS gene (i.e. had only motor tics or vocal tics, or neither). Of 90 females over the age of 18 presenting with TS, or with motor or vocal tics alone, nine had severe agoraphobia with panic attacks. There may be genetic subtypes of both obsessive-compulsive disorder and agoraphobia with panic attacks that are due to partial expression of the TS gene.

Gilles de la Tourette's syndrome (TS) is an hereditary (Eldridge *et al*, 1977; Nee *et al*, 1980) neuropsychiatric disorder, with the onset between 2 and 15 years of age of multiple motor tics and vocal noises that wax and wane in type and severity. The symptoms can be suppressed for variable periods of time, and must be present for at least one year (American Psychiatric Association, 1980; Shapiro *et al*, 1978; Friedhoff & Chase, 1982). Associated symptoms, not present in all cases, include coprolalia, echolalia, paralalia, attention deficit disorder (ADD) with or without hyperactivity (Comings & Comings, 1984; Cohen *et al*, 1983), learning disorders, exhibitionism (Eldridge *et al*, 1977; Comings & Comings, 1982, 1985), obsessive-compulsive behaviour (Eldridge *et al*, 1977; Nee *et al*, 1980; Shapiro *et al*, 1978; Friedhoff & Chase, 1982; Comings & Comings, 1985; Montgomery *et al*, 1982; Jagger *et al*, 1982), discipline and behaviour problems (Comings & Comings, 1985; Wilson *et al*, 1982), and stuttering. The TS gene can be partially expressed in the form of chronic motor tics alone or vocal tics alone (Eldridge *et al*, 1977; Nee *et al*, 1980; Kidd & Pauls, 1982; Baron *et al*, 1981; Comings *et al*, 1984) and possibly ADD alone (Comings & Comings, 1984). The present study is part of an analysis of 250 cases of TS in which detailed pedigrees were obtained. Complex segregation analysis of these cases for the combined Gilles de la Tourette's syndrome and chronic multiple tic disorder (TS-MT) indicated the involvement of a major gene and excluded polygenic inheritance for a population frequency of the TS-MT trait of less than 1.2% (Comings *et al*, 1984).

We present here some of the pedigrees in this series in which relatives of the TS probands had panic attacks with agoraphobia, or obsessive-compulsive behaviour, but had only motor tics, only vocal tics, or no tics (i.e. did not express the full Gilles de la Tourette syndrome). Since the partial expression of TS, or a family history of TS, can be easily missed unless specifically looked for, we feel these observations may be of value in the further definition of subtypes and causes of agoraphobia and of obsessive-compulsive behaviour.

There is increasing evidence for a significant genetic contribution to panic attacks (Pauls *et al*, 1979 *a*, *b*, 1980; Carey & Gottesman, 1981; Pariser *et al*, 1979; Crowe *et al*, 1983; Harris *et al*, 1983) and panic attacks with agoraphobia (Cohen *et al*, 1951). In a study of 41 probands with panic disorder and 41 controls, Crowe *et al* (1983) found panic disorder or probable panic disorder in 25% of first-degree relatives in the first group, compared with 2% in the controls. In 61% of the families, panic disorder was familial; 11% of the probands also had agoraphobia. These figures are comparable to those of Cohen *et al* (1951), who found that 22% of first-degree relatives were affected and that 67% of the cases were familial. Harris *et al* (1983) found that the frequency of agoraphobia was twice as high in first-degree relatives of probands with agoraphobia than in controls, and concluded that agoraphobia was a familial disorder.

The frequency of obsessive-compulsive disorder is also significantly greater among first-degree relatives of patients with obsessive-compulsive disorder than in the general population (Cohen *et al*, 1951; Kringlen, 1965; Rutter, 1966; Carey, 1978; Cary & Gottesman, 1981). Four identical twin pairs, all concordant for obsessive-compulsive disorder, have been described in which the monozygosity and diagnoses were clearly established (Marks *et al*, 1969; Woodruff & Pitts, 1964; Black, 1974; McGuffin & Mawson, 1980). In two of these the illness occurred at a time when the twins were separated and had little

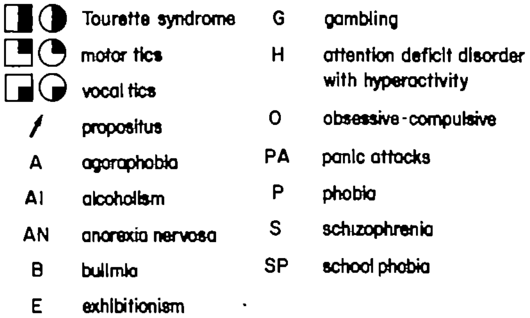

FIG. 1 Key for Figs 2–6

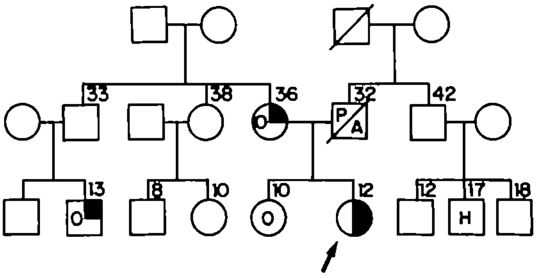

FIG. 2 Pedigree No. 68 (see Fig. 1 for key)

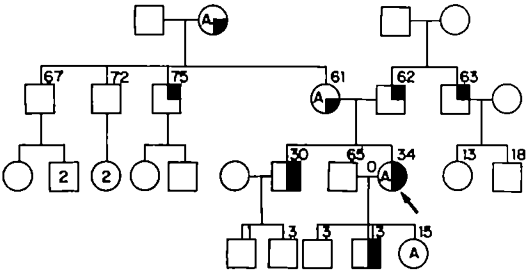

FIG. 3 Pedigree No. 74 (see Fig. 1 for key)

contact with each other (McGuffin & Mawson, 1980). In all four sets, one parent also had an obsessive-compulsive disorder.

Based on an ongoing study of 51 pairs of monozygotic and dizygotic twins, Cary & Gottesman (1981) concluded that "heredity plays a significant part in obsessional disorder and in the phobics who are severe enough to warrant psychiatric care".

Method

The following pedigrees are taken from a series of 250 consecutive cases of Gilles de la Tourette's syndrome, seen in the TS clinic at the City of Hope Medical Center. The clinical, epidemiological, genetic, and other psychiatric aspects of these cases have been presented elsewhere (Comings *et al*, 1984; Comings & Comings, 1984, 1985). All cases conformed to the six criteria of DSM-III, except for nine who did not have vocal tics, but were typical in every other way, and had four or more motor tics. The family pedigrees were based on personal interview (using a structured questionnaire) and examination of every propositus and of every affected first-degree relative. Whenever any other affected relative was geographically available, they were also examined; whenever available, prior medical records were obtained on affected individuals. All patients with agoraphobia had agoraphobia with panic attacks by DSM-III criteria. The obsessive thoughts and behaviour are as described in the case reports.

Case reports

A key to Figs 2–6 is given in Fig. 1.

Pedigree No. 68 (Fig. 2). The ten year-old sister of this propositus had to count to ten many times a day, while taking small steps. The mother had rapid eyeblinking as a child; if she touched one finger, she had to touch them all, and if she touched one tooth with her tongue, she had to touch them all. She had obsessive thoughts in the form of drawing in her mind a square with a cross inside. However, her rules were that she could not lift the pencil from the imaginary paper and could go over a given line only once. Since this is impossible, she dwelled on it constantly, up to 50 times a day. Her 13 year-old niece had hand tics and also took many small steps and counted them. The propositus' father had some panic attacks while driving, a few years before he died of a cerebral aneurysm, but since he had no symptoms of TS he is not included in this series.

Pedigree No. 74 (Fig. 3). The propositus was a 34 year-old female who had an onset of facial tics, grunting, and squeaking at the age of four; mental coprolalia started at the age of ten. At the time of study she had facial and head tics and squeaking vocal noises. She sometimes had to read things a dozen times before it sank in, and complained of racing thoughts and trouble with recent memory. She had obsessive thoughts of sex, violence (killing her mentally retarded son, running her car into a cement wall at 100 mph),kleptomania, and self-destructive acts (cutting off all her hair, cutting herself). She had a responsible job, but had to leave it because of panic attacks while driving; during these she hyperventilated, perspired, had chest pain, felt faint, was tearful, was afraid, and wanted to scream and run away. They came on suddenly, without warning, under a wide range of conditions; this resulted in severe agoraphobia. She had compulsive counting of the number of letters in words, and made mental lists of words according to the number of letters in them. Objects had to be in exactly the right place. Her mother had constant throat clearing and letter reversal in spelling, and experienced panic attacks and agoraphobia for many years; her thoughts also raced, and she was forgetful. Her maternal grandmother also had panic attacks with agoraphobia, and throat clearing. In the six months before the study her daughter, then 15, had panic attacks on elevators, escalators, and while driving, and was increasingly afraid of leaving the house.

Pedigree No. 75 (Fig. 4). The nine year-old sister of this propositus had intermittent facial tics and did numerous

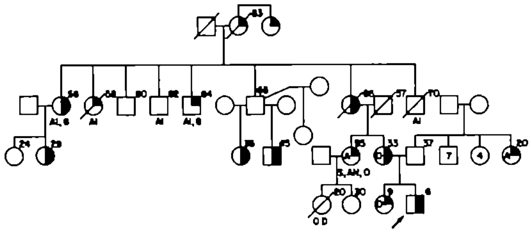

FIG. 4 Pedigree No. 75 (see Fig. 1 for key)

things in a compulsive manner such as touching her head to the ground, or putting both feet together, touching her head, and stiffening up. The father had a 20 year-old sister who had eyeblinding from ages 9 to 12, and who had recently had panic attacks and was afraid to leave the house. The mother was hyperactive as a child, had mild motor and vocal tics from the age of 6 to 15, and compulsively smelt objects. Her 55 year-old sister had multiple psychiatric problems. She was admitted to the hospital on eight occasions, and received chlorpromazine and ECT for schizophrenia. Although medical records were not available, ten of our TS proposita were incorrectly diagnosed as schizophrenic, and she may have been so as well. She had anorexia nervosa as a teenager, has been agoraphobic for the past 20 years, and was obsessive about repetitive touching, smelling, and sniffing. The maternal grandmother had a life-long history of throat clearing, coprolalia, spitting, and facial tics. The remainder of the family history is shown in Fig. 4, and includes four other individuals with TS, four with motor tics, five alcoholics, and two compulsive gamblers.

Pedigree No 76 (Fig. 5). The mother of this 14 year-old boy with TS, ADD, and exhibitionism had vocal noises and facial tics as a child. She had compulsive behaviour, consisting of vacuuming the house many times a day, every day. She had had severe agoraphobia with panic attacks for five years, and was unable to come to the clinic unless someone brought her. She took diazapam to relieve her anxiety about being on the motorway.

Pedigree No 184 (Fig. 6). The father of a 16 year-old boy with TS and ADD had a "nervous breakdown" at the age of 40; he then began having panic attacks when driving, and developed severe agoraphobia. He did not leave the house for years and still has difficulty with panic attacks when he goes out. He tried to keep his business going for five years by phone, but it eventually collapsed and he is now on a total disability pension. He was also hyperactive as a child, but had no tics or vocal noises. The 57 year-old sister developed severe agoraphobia with panic attacks at age 32, and still has these problems. She had three children, including a 26 year-old son who had such severe school phobia that he required home tutors.

Pedigree No. 192. The mother of a 15 year-old boy with TS had grunting vocal noises, rapid eyeblinking, and facial tics for several years as a child. At the time of study she had panic attacks and felt paralysed when driving on the motorway, and had to have others drive for her. She had a 17 year-old brother with head tics, eyeblinking, vocal noises, coprolalia, learning disorders, short temper, and a paranoid personality. The parents are divorced. The father had a head tic as a child.

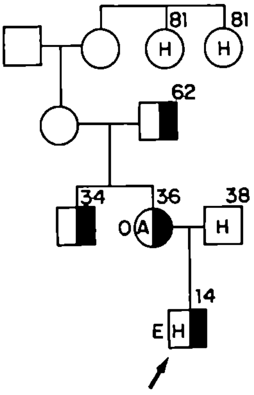

FIG. 5 Pedigree No. 76 (see Fig. 1 for key)

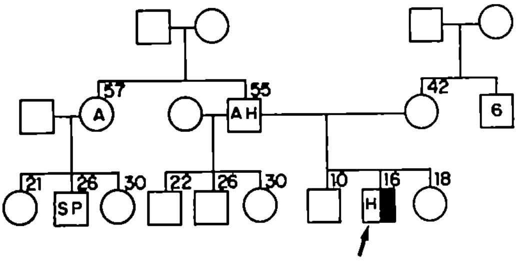

FIG. 6 Pedigree No. 184 (see Fig. 1 for key)

Pedigree No. 316. The mother of identical twin girls with TS had severe mental coprolalia for years, and was afraid she would say the word 'fuck' out loud. She had a compulsion to fold and unfold the pages of books and could sit doing this for hours; if she went somewhere without a book she felt uncomfortable until she had one in her hands again. She had an obsession with dates, fixing on the day's date and saying it over and over in her mind, hundreds of times; she combined the compulsion and obsession by carrying around a diary. She had numerous panic attacks over many years, and felt tense and nervous unless at home; this was slowly getting worse. There had been problems with stuttering since childhood.

Pedigree No. A1. A 40 year-old female was referred because of familial agoraphobia. She had an onset of panic attacks with associated agoraphobia at the age of 22 and has had attacks almost daily ever since, despite years of varied types of therapy. In the past year she has obtained significant improvement of symptoms with medication (alprazolam). Her mother had suffered from agoraphobia with panic attacks since the age of 24, and the maternal grandmother and grandaunt also had agoraphobia. The propositus had a 14 year-old son with an onset of eyeblinking, facial grimacing, head jerking, and hyperactivity at two years of age; he later developed ritualistic licking of his shoulders and feet, paralalia, numerous phobias, and obsessive-compulsive behaviour. Except for the absence of vocal noises, he was a classic, undiagnosed case of TS. In this family, the TS was ascertained through a patient with agoraphobia, rather than vice versa.

Discussion

Many studies have shown the presence of an obsessive-compulsive disorder in individuals with TS (Eldridge *et al*, 1977; Nee *et al*, 1980; Shapiro *et al*, 1978; Cohen *et al*, 1983; Comings & Comings, 1985; Montgomery *et al*, 1982; Jagger *et al*, 1982). Although Shapiro *et al* did not find evidence of a greater frequency of obsessive-compulsive behaviour in TS patients than in a general psychiatric clinic, its presence in up to two-thirds of TS patients in some series suggests a significant increase compared with the general population. The pedigrees studied here suggest not only that may TS patients themselves manifest an obsessive-compulsive disorder, but that their first and second-degree relatives may also present with such behaviour in the absence of full-blown TS. We believe this may constitute a genetic subtype of obsessive-compulsive disorder, due to the incomplete expression of a TS gene. Montgomery *et al* 1982 also reported (in a selected population of TS patients) the presence of obsessive-compulsive disorder and panic attacks, without tics or vocal noises, in first-degree relatives of patients with TS. The presence of an obsessive-compulsive disorder in first-degree relatives with either very mild motor or vocal tics, or no tics, is important in that it tends to negate the theory that this behaviour in TS patients is simply a psychological reaction to the presence of tics and vocal noises (Shapiro *et al*, 1972).

In this series of families there were 463 individuals manifesting the TS-MT gene by the presence of chronic motor tics, vocal noises, or both; nine of these (2.0%) had agoraphobia. (There were nine additional cases–five females and four males – in other relatives, but without tics or vocal noises; these are excluded from the 463 cases since there is no direct evidence that they also had the TS gene, although in six of them other members in that branch of the family showed complete or partial manifestation of the TS gene). Many of the 463 cases were less than 18 years of age. Agoraphobia usually has an onset between 18 and 35 years of age and affects primarily women, with a sex ratio of one male to nine females (Burns & Thorpe, 1977; Marks & Hearst, 1970; Mathews *et al*, 1981). If all patients younger than 18 years are excluded, there were 231 patients manifesting the TS-MT gene with motor or vocal tics or both. Of these, 141 were men. None of the men had agoraphobia (although some had panic attacks without agoraphobia); of the ninety women, nine had agoraphobia with panic attacks.

While the frequency of agoraphobia in females manifesting with TS-MT appears to be greater than that of the general population, the degree to which it is greater depends on which frequency figures are used for the general population. If the figure of one per 1000 of agoraphobia among women sufficiently severe to cause disability (Mathews *et al*, 1981; Agras *et al*, 1969; Hollingshead & Redlich, 1958; Lemkau *et al*, 1942) is used, agoraphobia is 100 times more common in women with TS-MT. If a higher estimate of 1.8% of women having agoraphobia-panic attacks (Uhlenhuth *et al*, 1983) is used, the rate observed here is only about five times that in the general population. The highest frequency we could find in any control series was 4.2% among relatives of 20 surgical patients and hospital employees, reported by Harris *et al* (1983).

There are several possible explanations of these data. Firstly, females carrying the TS gene, whether they have tics and vocal noises or not, might have an increased susceptibility to agoraphobia. Secondly, if females carrying a TS gene also inherit a gene (or genes) for panic attacks, they might be more likely to have panic attacks and agoraphobia than if they only had the gene for panic attacks. Thirdly, the TS gene and agoraphobia, whatever its cause, might be unrelated, and agoraphobia might be no more common in individuals with the TS gene than the general population. Our bias is towards the first explanation, but these issues will probably only be resolved by the development of genetic markers for the specific disorders.

We believe these observations are important for several reasons. Firstly, in most of these patients with incomplete expression of TS, the motor or vocal tics may no longer be present, may be relatively mild, or may be easily suppressed during an out-patient visit. As such, they are easily missed unless the patient is specifically questioned about them. Secondly, patients with agoraphobia or obsessive-compulsive behaviour should be questioned about the presence in relatives of motor or vocal tics, or both, as well as about agoraphobia and obsessive-compulsive behaviour.

Both the literature and the above observations suggest that agoraphobia and obsessive-compulsive behaviour may be subdivided into the following categories: (a) sporadic (no family history); (b) familial (positive family history); and (c) cases possibly due to a TS gene (positive history of motor or vocal tics in the patient or family members). This subdivision may have important implications about the best form of therapy for that individual.

Depressed Mood After Stroke

A Community Study of its Frequency

D. T. WADE, J. LEGH-SMITH AND R. A. HEWER

A community study on stroke registered 976 patients. Over 60% of survivors at three weeks, six months and 12 months after the stroke were assessed for depressed mood, using the Wakefield self-assessment depression inventory, and on other functional and social activities. At each point, 25–30% of those assessed were depressed; over 50% of patients depressed at three weeks remained so at one year. Factors associated with depression included loss of functional independence, a low level of other activities, a low reasoning ability, and being female and living with someone; path analysis showed that most depression was not explained by these factors. Few depressed patients at six months were on antidepressant medication.

The physical disability caused by stroke is obvious but, despite the attention drawn to the "hidden barriers to recovery" (Adams, 1974), little attention has been paid to the emotional aspects of stroke. Reasons may include the difficulty in assessing emotion accurately, and the feeling that it is only to be expected that stroke patients will be depressed. It is only in the past few years that the frequency of depression after stroke has been investigated. One group have found depression to be present in about 30% of patients (Robinson & Price, 1982; Robinson *et al*, 1983); they have suggested that it may be specifically associated with localised damage near the left frontal lobe (Robinson *et al*, 1984*a*) and that treatment with nortriptyline may relieve it (Lipsey & Robinson, 1984). A second group also found depression in about 30% of patients, and related this to their loss of social activities (Feibel & Springer, 1982).

The pioneering work of these two groups of investigators needs to be replicated. We have investigated the frequency of depressed affect after stroke in a community survey. In this paper we examine the following questions:

(a) How prevalent is depression at various times after stroke?

(b) What is the natural history of depression after stroke?

(c) What factors relate to the presence of depression at any time?

Method

Over 28 months, a total of 976 acute cases were registered in a community survey of stroke-related disability, based on a population of 215 000 patients registered with 96 general practitioners in Bristol. Of these, 249 patients (26%) were not admitted to hospital over the first six months after the stroke. Patients were identified by direct notification from anyone involved in stroke care (e.g. family or hospital doctors, nurses, therapists) and also by obtaining the records of all patients known to have been discharged from any hospital in the county of Avon with a primary or secondary diagnosis of stroke (ICD-9 classifications 430–438; World Health Organisation, 1978). A clinical diagnosis was used for this study, based upon the WHO definition (Aho *et al*, 1980): "Rapidly developed clinical signs of focal (or global) disturbance of cerebral function, lasting more than 24 hours or leading to death, with no apparent cause other than of vascular origin". The diagnosis was confirmed by a neurologist, by personal examination in 713 (73%) cases or by reading hospital notes if a patient had died or was registered late.

Each patient was seen as soon as possible after the stroke, at 3 weeks, at 6–7 months, and at 12–13 months; at each point, information was recorded on many aspects of the neurological, functional, emotional, and social status.

Depression was assessed using the Wakefield self-assessment depression inventory (Snaith *et al*, 1971), which has 12 questions giving a score between 0 and 36; although not validated in the elderly or in stroke, it was derived from the Zung scale, which has been validated in stroke research (Robinson & Price, 1982). In the original validation, a score of 15 or more was found to be the best cut-off to identify those with depression. We have classified those scoring 15–18 as exhibiting 'probable depression' and 19–36 as 'definitely depressed', because there is some evidence that older people tend to have higher scores (Snaith *et al*, 1971). The Hopelessness scale (Beck *et al*, 1974), comprising 20 statements for the patient to agree or disagree with, was also used, but many found it difficult to understand, and so the results were only used to help validate the Wakefield scale. Since the Wakefield inventory was not developed as an accurate diagnostic instrument, but rather as a way of assessing the severity of depression, our results concern the

TABLE I
Characteristics of 976 patients studied

		Time	
	3 weeks	*6 months*	*12 months*
Died: *n*	350	432	484
Notified late/lost to follow-up: *n*	57	69	58
Aphasic or confused: *n*	190	98	86
Assessed for depression: *n*	379	377	348
Average age: years			
Mean	69.9	69.7	69.3
s.d.	9.6	9.8	10.3
Male: *n*	203 (54%)	209 (55%)	180 (52%)
Living alone: *n*	87 (23%)	88 (23%)	92 (26%)
Not admitted in 6 months after stroke: *n*	159 (42%)	165 (44%)	151 (43%)
Side of weakness: *n*			
Right	170 (45%)	174 (46%)	160 (46%)
Left	178 (47%)	166 (44%)	152 (44%)
Both or neither	31 (8%)	37 (10%)	36 (10%)
Disability–Barthel scores: *n*			
0–14 (severe/moderate)	99 (26%)	48 (13%)	45 (13%)
15–19 (mild)	123 (32%)	128 (34%)	117 (34%)
20 (no disability)	157 (42%)	201 (53%)	186 (53%)
Depression–Wakefield scores			
0–14 (not depressed)	252 (67%)	257 (68%)	240 (69%)
15–18 (probably depressed)	43 (11%)	46 (12%)	45 (13%)
19–36 (depressed)	84 (22%)	74 (20%)	63 (18%)

extent of any feeling of depression or sadness, rather than clinically defined 'depression'.

Social function was assessed using the Frenchay Activities Index (FAI) (Holbrook & Skilbeck, 1983); this records the frequency with which a patient has performed various activities over the preceding months, and gives a score ranging from 0 (no participation) to 45 (full participation in all 15 items). Physical function was measured using the Barthel Activities of Daily Living (ADL) scale (Granger *et al*, 1979). This scale measures ten self-care items, and gives a score of 0–20. A score of 0–9 indicates 'severe' disability; 10–14, moderate disability; 15–19, 'mild' disability; and 20, functional independence. Each patient's reasoning ability (IQ) after the stroke was measured using Raven's coloured progressive matrices (Raven, 1965): this is a non-verbal measure with normative data for the elderly. Motor loss was assessed using the Motricity index (Demeurisse *et al*, 1980), which gives a score ranging from 0 (complete paralysis) to 100 (normal strength). Two self-assessment procedures were also used. Firstly using a visual analogue scale 150 mm long, patients were asked to indicate the degree of recovery of independence they had achieved: the end-points were "the worst you were with your stroke" and "as you were before your stroke". Secondly, using a five-point scale, patients were asked to indicate their depression relative to before their stroke as much less, less, the same, more, or much more (scored 1–5).

Results

Details on the patients seen and time-point assessed are shown in Table I. Patients with a wide range of disabilities and ages were included. The number of patients not assessed due to late notification, and because of communication problems (either aphasia or confusion) is also given. Only ten patients refused to answer the questions. The high proportion of patients not admitted reflects the fact that many of those admitted were severely affected, and died within a short time. The prevalence of a depressed affect at three weeks, six months and one year is also shown: approximately 20% of patients were 'definitely depressed' at any point, and a further 10% 'probably depressed'. The Hopelessness scale was completed by 317 patients at one year: their average score was 5.64 (s.d. 4.02), ranging from 0 to 19, with only 26 scoring 13 or more.

Recovery from depression did occur. Of the 127 scoring 15 or more on the Wakefield scale at three weeks, 26 had died by six months, and a total of 46 had died by one year. At six months, 33 (33%) of the surviving 101 patients scored 14 or less. At one year, 28 (35%) of the surviving 81 patients were not depressed.

To determine how much variability occurred with time, details of the 255 patients with assessments at all three points were analysed: 175 (69%) scored 0–14 at three weeks and 80 (31%) scored more than 15; 133 (52%) were consistently

TABLE II

Some correlation coefficients with Wakefield scores (all significant at $P<0.01$)

	n	*Coefficient*
At 3 weeks		
Barthel ADL score	379	−0.329
IQ (Raven's matrices)	331	−0.257
Motricity score	342	−0.324
At 6 months		
Barthel ADL score	377	−0.219
IQ (Raven's matrices)	345	−0.146
Current social activities (FAI score)	375	−0.353
Loss of social activities (FAI score)	357	+0.229
Carer's depression (Wakefield)	192	+0.345
Self-image of recovery (line scale)	293	−0.430
Self-image of mood change	359	+0.539
At 1 year		
Barthel ADL score	348	−0.247
IQ (Raven's matrices)	330	−0.203
Current social activities (FAI score)	348	−0.371
Carer's depression (Wakefield)	200	+0.253
Other correlations		
Wakefield 3 week and 6 month scores	312	+0.690
Wakefield 3 week and 1 year scores	261	+0.630
Wakefield 6 month and 1 year scores	299	+0.750
Wakefield 6 month and Barthel 3 week scores	365	−0.165

'not depressed', while 44 (17%) were consistently 'depressed' at all three points. Thirty-nine (15%) depressed patients had recovered by one year, but 14 (5%) who were not initially depressed became so by six months, while 25 (10%) became depressed by one year; 19 (7%) patients fluctuated between the three assessment points.

One can conclude that approximately half of the patients who were depressed at one year had been depressed since soon after their stroke. Also, a quarter of those not initially depressed became so six months to one year later.

To elucidate the factors associated with depression, simple correlation coefficients were calculated between a patient's Wakefield score and his score on other scales (Table II). A few patients had to be excluded, as data for them were not available, but most analyses contained over 300 patients. All coefficients are statistically significant ($P<0.01$), with the highest associative factors of items not measuring mood being self-image of recovery ($r=-0.430$) and FAI score at one year ($r=-0.371$). The negative sign indicates that as these scores increase, so less is scored on the Wakefield Depression Inventory (i.e. showing a less depressed mood). Similarly, as functional and intellectual performance improve, showing higher scores, so Wakefield score decreases. However, these coefficients are not high enough to imply necessarily clinical significance; e.g. the Raven's progressive matrices score at six months only accounts for 2% of the variance seen, despite its statistically significant coefficient of $r=-0.146$. Furthermore, the existance of a significant correlation cannot be assumed to indicate a causal relationship.

The strongest correlations are those between measures of mood, either using different instruments (e.g. the Hopelessness scale) or at different times. Wakefield scores are also strongly correlated with patients' self-assessment of mood change from before their stroke.

At three weeks after the stroke there was a significant association ($\chi^2=7.56$, $P<0.05$) between depression and side of stroke symptoms: 75 (42%) of the 178 patients with left-sided symptoms were probably or certainly depressed, compared with 48 (28%) of the 170 patients with right-sided symptoms. Their mean scores were significantly different (left $=13.1$, s.d. $=8.6$; right $=11.2$, s.d. $=7.8$; $t=2.17$; $P<0.01$). The mean score (8.3, s.d. $=7.1$) of the 31 patients with no unilateral symptoms or signs (e.g. brief or mild aphasia) was significantly lower than in the patients with left-sided symptoms ($t=2.94$, $P<0.01$). There was no significant association between level of depression and laterality of stroke at six months or one year. Patients with aphasia or other communication problems sufficient to preclude assessment – 86 (20%) at one year – were excluded. Most of these patients had right-sided weakness, which complicates interpretation of results.

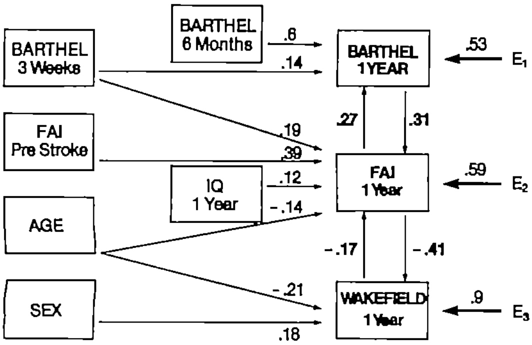

FIG. 1 Path diagram showing influences on depression, social activities and ADL in 348 patients seen one year after stroke.

Women appeared to be significantly more depressed at all three assessment points ($P<0.01$). The number of men/women scoring 19 or more (certain depression) was 38/46 (19%/26%) at three weeks; 29/45 (14%/27%) at six months, and 28/35 (15%/21%) at one year. This sex difference was not simply because more women lived alone: at one year, the mean score of the 45 women living alone was 10.3 (s.d. = 7.2), identical to that of the 27 men living alone. In fact, the difference in depression was most marked in those living with someone: the 180 men had a mean score of 9.7 (s.d. = 7.1), as against 12.0 (s.d. = 7.6) for the 121 women ($t=2.44$, $P<0.02$). The remaining patients were in institutional care. Overall, there was no significant difference in average depression scores between the patients living alone and those living with someone.

Few patients were on treatment for depression six months after the stroke. Information on drugs being taken was available for 274 of the patients assessed, but this information had not been collected for those seen in the early part of the study. Only 23 (8%) were on antidepressant medication; their average Wakefield score was 14.9 (s.d. = 8.0), which was significantly higher ($t=2.35$; $P<0.01$) than the remaining patients (mean = 10.8; s.d. = 8.0). Eleven (48%) had scores of 15 or more, compared with 76 (30%) of the remaining patients, 50 of whom had scores of 19 or more. It seems that most 'depressed' patients were not being treated for depression.

Path analysis (Blalock, 1971) was used to develop a model linking the various factors thought to influence depression: as results were very similar after both six months and one year, only the latter are illustrated in Fig. 1. This technique allows a visual appreciation of the associations between several variables simultaneously. Repeated multiple regression analyses identify the strength of interactions between pairs of variables, while controlling for the effects of the other variables. Path coefficients (i.e. standardised regression coefficients) represent the relative strength of each association.

Figure 1 illustrates the influences on a patient's mood (Wakefield), social function (FAI), and functional ability (Barthel ADL) at one year after the stroke. The arrows to these variables, together with corresponding path coefficients, indicate the relative (but not absolute) strength of influence of static or preceding factors. For example, 'sex' indicates that, when controlling for all other factors, sex has a relatively small influence on depression.

The path diagram further illustrates how a significant correlation, for example that between ADL score and Wakefield score ($r=0.247$), can be 'lost' when controlling for other variables. That is, the path coefficient between ADL and Wakefield scores did not reach a significant level (zero path coefficient), and was therefore ommitted from the diagram. The significant correlation can now be explained by means of an intervening variable – FAI – which may act as a mediator between ADL and depression.

Where reciprocal statistical influences exist between outcome variables, these have been indicated; it is difficult, however, to envisage how social functioning might influence ADL function, and an unidentified intervening variable must be assumed. The consequence of depression in terms of fewer activities (lower FAI score) and vice versa is, on the other hand, more readily understood.

Finally, in understanding the three outcome factors, much of the variance has not been accounted for in terms of the variables measured, so that unmeasured extraneous variables must account for the remainder; 28% of the variance in Barthel ADL is unaccounted for, and extraneous variables are represented by E_1 in the diagram with a path coefficient of 0.53. Similarly, 25% of the variance in FAI (E_2) and 40% of the variance in Wakefield (E_3) are unaccounted for.

Discussion

This analysis confirms that a depressed mood is common after stroke and shows that, although other stroke-induced losses do relate to depression, most depression cannot be explained simply by reference to physical or social disability. One possible explanation is that pre-existing personal or social characteristics may have an important influence on the presence of depression after stroke. It also seems that few depressed patients receive specific medical treatment, despite evidence that tricyclic antidepressants may be effective (Lipsey & Robinson, 1984).

This study included all patients admitted to hospital, but might have missed some of those treated at home; however, our overall incidence of 1.90/1000 per year is not very different from other surveys (aho *et al*, 1980), suggesting relatively complete notification. At one year after stroke, 88% of surviving patients were seen, but 20% of these could not be assessed due to communication problems. Although 'objective' biochemical methods of diagnosing depression have been proposed (Carroll *et al*, 1981), their sensitivity and specificity are still debated (Holden, 1983), while their use in a community study would raise many problems. However, as a wide spectrum of patients was included, with no obvious selection according to stroke severity or hospital admission, the sample should be representative of patients suffering stroke but with no communication problems.

The validity of the Wakefield depression scale needs discussion. In this study, the Wakefield score was strongly related to two other measures of depression–the Hopelessness score and the patient's own assessment of his mood change–and it was also related to the prescription of antidepressant medication. We conclude that the Wakefield did measure depressed mood in our patients, although this is not to say that patients with a depressed mood necessarily suffered a depressive illness.

Patients were categorised as 'probably' or 'certainly' depressed because of uncertainty as to cut-off values with an elderly population. Furthermore, it is possible that many 'normal' elderly people are 'depressed': the average Hopelessness score of 5.64 in our study is not significantly different from that recorded in 148 normal people aged over 50 in Dublin (Greene, 1981). Depression may have been present in many patients before their stroke. However, one survey (Bergmann, 1982) of elderly people suggested that 'depressive neurosis' was present in only 3.8% of the 360 tested and 'depressive illness' in 0.6% (all women). These figures are much lower than those seen in our patients with stroke.

Our results confirm the frequency of depression found in other large-scale studies (Robinson & Price, 1982; Robinson *et al*, 1983, 1984*b*; Feibel & Springer, 1982): approximately one-third of patients were depressed at any time after the stroke. We found that the severity of the stroke, as measured by the Barthel ADL scale, did have a direct correlation with depression. One other study (Feibel *et al*, 1979,) noted such a correlation, although the strength of their correlation increased with time, in contrast to the fall we found; other studies (Robinson & Price, 1982; Feibel & Springer, 1982) failed to find any correlation with ADL loss. Two points need to be made concerning this correlation. Firstly, when present, it is relatively small, accounting for 5–15% of all variance; this is probably not clinically important. Secondly, path analysis suggests that non-ADL activities are intervening factors in the relationship between ADL function and depression. We thus confirm the relationship between depression and low social functioning, as previously found (Feibel & Springer, 1982; Feibel *et al*, 1979).

It has not previously been reported that women are more depressed; this difference applied only to those living with someone. Social isolation did not appear to be associated with depression. The other major identified influence on depression at one year was depression seen earlier in the recovery process. Over half of those depressed at three weeks or six months were still depressed at one year. This is a little less than found in another follow-up study, where 10 out of 13 initially depressed patients were still depressed at six months (Robinson *et al*, 1984*b*).

Previous reports on small numbers of selected patients (Robinson *et al*, 1984*a*) have suggested that there is a higher rate of depression in those with lesions in the left frontal region, but the same workers failed to confirm this finding when studying larger groups of patients (Robinson *et al*, 1983). We did not have any information concerning the anatomical location of the stroke, but we have failed to confirm any association between right-sided weakness and depression. Indeed, in the first few weeks those with left-sided weakness were more depressed, although this may be due to exclusion of patients with aphasia. We conclude that even if lesions near the left frontal pole are associated with an increased risk of depression, this cause of depression is overshadowed by other factors in the majority of cases.

This study confirms previous observations that most depression is untreated (Robinson & Price, 1982; Feibel *et al*, 1979,) and also shows that most depression cannot be explained simply as a natural response to physical disability. Indeed, much of the variance in depression is unaccounted for by any of the variables studied, suggesting that other personal or social factors may be important. This study suggests that attempts to reduce depression through improving a patient's social or ADL functioning may not be very successful, although this is not to deny the important association between depression and both low social and ADL functioning.

In conclusion, this study found that a depressed mood was present in about one-quarter of surviving and assessable patients at any time up to one year after stroke. Less than half of those depressed in the early stages were free of depression at one year. The presence of depression was associated with the degree of physical disability, loss of social function, and being female living with someone, but these and other factors measured do not account for much of the depression seen. The path diagram derived from these data gives a broad outline, in visual form, of some important inter-relationships, but will need modification in the light of future research.

Acknowledgements

We acknowledge the full co-operation of all those whose patients we studied, and the patients and their families. We are grateful to the Chest, Heart and Stroke Association, who funded Mrs J. Legh-Smith, and to the Department of Health and Social Security who funded the remainder of this research.

Correlation between the 37-Item Mental Test Score and Abbreviated 10-Item Mental Test Score by Psychogeriatric Day Patients

P. THOMPSON and G. BLESSED

Groups of organically and functionally mentally ill psychogeriatric day patients were assessed by the 37-item Roth-Hopkins test and the abbreviated ten-item Roth-Hopkins test. The scores correlated highly, correlation being equally good for both diagnostic groups. Among the functionally ill and the mild organically ill, scores improved between first and second test. The quicker, better tolerated ten-item test is a useful test of mental impairment for psychogeriatric patients in the community, as well as in institutional care.

A mental test of orientation and information was devised by Roth & Hopkins in 1952, and shown to distinguish between diagnostic groups of organically impaired and functionally disordered elderly psychiatric patients (Roth & Hopkins, 1953; Hopkins & Roth, 1953). It was modified by Blessed *et al* (1968), who added tests of memory and concentration previously shown by Shapiro *et al* (1956) to distinguish between similar categories of patients. This 37-item Roth–Hopkins mental test score (MTS), when applied to elderly psychiatric patients who were followed to post-mortem, was shown to correlate significantly with quantified measures of cortical degeneration and with levels of choline acetyl transferase in the neo-cortex (Blessed *et al*, 1968; Perry *et al*, 1978).

Hodkinson (1972) and Qureshi & Hodkinson (1974) developed an abbreviated form of MTS which condensed the most discriminating aspects of the MTS to ten items (AMTS). They showed with patients recently admitted to hospital, in long-stay wards, or in residential homes, that the AMTS was quicker to perform, better tolerated by patients, and correlated highly significantly with both the MTS and the Modified Tooting Bec questionnaire—a further test of cognitive function used extensively in the assessment of memory and orientation in elderly patients (Denham & Jeffreys, 1972). Qureshi & Hodkinson administered the AMTS twice to 72 patients, and found no evidence that patients' performance improved with practice.

This study was carried out to select a suitable test for rapid screening of elderly people living in their own homes for signs of dementia. In seeking a test, the authors chose the AMTS because it contains only items from the MTS, which has the advantage—rare among clinical tests of cognitive function—of having been validated against neuropathological and neurochemical changes in the brain. However, in the previous studies, the AMTS had been administered to institutionalised patients only, and it was felt necessary to show that inter-test correlation was equally high for patients living in their own homes.

Method

Fifty-two patients living in the community but currently attending a psychogeriatric day hospital for treatment were selected for testing if they satisfied the following criteria:

1. They were willing to participate.
2. They had completed a full diagnostic assessment procedure.
3. They were attending at least once per week, so that both tests could be administered within seven days of each other.
4. They could hear well enough to participate in testing, and speak sufficiently clearly for their answers to be recorded.
5. Their psychiatric disorders could be reliably classified by the International Classification of Diseases (ICD-9) criteria (WHO, 1978), on the basis of the history of the illness, previous psychiatric and family history, and in certain patients, electro-encephalographic and radiographic examination, more complex psychometry, etc. Those with ambiguous or mixed diagnoses were excluded.

Patients were allocated at random to two groups: one group had the MTS (Appendix I) followed by the AMTS (Appendix II) at their next attendance. The other group received the AMTS first and the MTS subsequently. Possible improvement of scores over time was looked for by assigning a score (MTSA) derived from the performance of the patient on the ten items of the AMTS as they occur in the 37-item MTS. A comparison of the first score on AMTS or MTSA was then made with the second score.

All tests were given by one interviewer, under identical conditions.

Results

All 52 patients completed the study; there were 13 men and 39 women, with a mean age of 75.75 (±6.82) years. There was no significant difference by sex or age between the two groups. The diagnoses of the patients are shown in Table I.

Twenty-seven patients had chronic organic brain syndrome (dementia), while 25 suffered from functional psychiatric illnesses. Comparison of test performances for these two major sub-groups is shown in Table II.

The functionally ill not only scored better than the organically ill, but were also consistently better, with much less individual variation. This is revealed in the histograms (Figures 1 & 2).

The organically ill seemed to fall into two groups of roughly equal size: 13 obtained scores equal to or greater than 75% correct answers, while the remaining 14 scored 70% or less correct. The former are referred to as 'mildly impaired' and the latter as 'moderately to severely impaired'. The organically ill group as a whole scored significantly worse than the functionally ill on both the MTS and the AMTS ($P<0.001$ for both tests).

The scores that patients attained on the AMTS correlated highly significantly with those of the MTS and the MTSA (Table III).

These correlations are comparable to those found by Qureshi & Hodkinson (1974), which ranged from +0.87 to +0.96.

By Sign Test analysis, it was found that all diagnostic groups except the moderately to severely organically ill improved from the first to the second test, reaching varying levels of significance (Table IV). This was unaffected by the period between tests (two to seven days).

TABLE I
Diagnoses of the patients

Diagnosis	*ICD 9*	*No*
Organic group	290	27
Senile dementia	290.0	20
Pre-senile dementia	290.1	1
Arteriosclerotic dementia	290.4	3
Other/unspecified	290.8–9	3
Functional group	295–8/300	25
Depression	296.1/298.0/300.4	20
Hypomania	296.4	1
Paraphrenia	295.3	1
Schizo-affective disorder	295.7	3
Total		52

TABLE II
The differences between the scores of two groups of patients

Discussion

The results of this study agree with those of Qureshi & Hodkinson, that the shorter, quicker AMTS correlates well with the MTS. No disadvantages of the AMTS came to light during the performance of the study; it was still possible to draw a more subjective appraisal of the patients in the quality of their answers. It was also felt subjectively that patients tolerated the shorter test better.

The 'assigned' MTSA correlated well with both the MTS and the AMTS and it seems valid to assign a score in this way. The effect of improvement in score shown by the functionally ill and the mildly organically ill was independent of age or sex, and is probably a result of a learning process, since in a period of less than seven days, it is unlikely that any improvement due to treatment had occurred.

This finding is at variance with that of Qureshi & Hodkinson, which is probably related to a greater number of their cohort being of the moderately to severely organically impaired category.

Despite the considerable differences in mean scores, on both tests, between functionally and organically impaired patients there is a considerable overlap between scores obtained by the functional group and by the mildly impaired of the organic group. This may reflect a group of patients with early dementia at the upper end of the range of cognitive ability who would progressively worsen. It may also be due to a group of organically ill patients whose cognitions are relatively spared and have been referred for other reasons. Under-education may play a part, but would be expected to affect all groups of patients equally (Bergmann *et al,* 1971). Whatever the reasons for this overlap, it appears that the mildly impaired have a capacity for improvement which is not demonstrable in the severely impaired.

The fact that improvement is possible supports the use of cognitive rehabilitation methods such as Reality Orientation Treatment for the less severely impaired (Woods, 1979), but also suggests that serial testing should be used with caution in mildly organically and functionally ill patients.

Thus, as in patients in institutional care, for a psychogeriatric day-patient who has been diagnosed on the clinical picture as suffering from an organic brain syndrome, the AMTS is a useful, commendably brief interview for quantifying the severity of the cognitive impairment, comparable to the MTS.

Mental tests alone cannot replace careful clinical assessment in the diagnostic process in psychiatry of the elderly. They remain an important adjuvant and, in this context, a brief test is preferable to a longer one of similar sensitivity and reliability. The AMTS appears to satisfy these criteria admirably.

Monoamine Oxidase Inhibitors and Narcotic Analgesics
A Critical Review of the Implications for Treatment

B. BROWNE and S. LINTER

There has been a recent renewal of interest in the use of monoamine oxidase inhibitors, but the concurrent administration of narcotic analgesics is often a cause for concern. This review clarifies the different types of MAOI/narcotic interactions and offers guidelines for the use of narcotic analgesics in the presence of MAOIs. The MAOI/pethidine interaction has two distinct forms: an excitatory and a depressive form. Pethidine must never be used in the presence of MAOIs because of the risk of a fatal excitatory interaction. Morphine does not cause this excitatory interaction, and is the drug of choice provided an allowance is made for possible potentiation of the depressive narcotic effect. It is inevitable that strong analgesia will occasionally be required as an emergency measure in patients on MAOIs, and insufficient attention is paid in psychiatric textbooks to the two different types of interactions and their therapeutic implications.

There has been a recent renewal of interest in the use of monoamine oxidase inhibitors (MAOIs) in this country, the USA (Quitkin *et al*, 1979) and Australia (Brown & Cass, 1979). As a British Medical Journal (1976) editorial put it, "This resurgence is timely. Other types of treatment for depression and phobias are far from satisfactory, especially in those patients who seem to respond to MAOI". Although the precise clinical indications remain unclear, they have potential application in anxiety states, phobic disorders, hypochondriacal and depressive neuroses, obsessional neuroses, and possibly more severe depressive illness (Tyrer, 1982).

The main concern in the clinical use of MAOIs relates to the risk of dietary and drug interactions, although in spite of many potential risks, problems are uncommon in practice when care is taken (Crammer *et al*, 1982). Nevertheless, when patients on MAOIs urgently require a narcotic analgesic for emergency surgery or the relief of severe pain there is concern about a potentially fatal interaction on the one hand, or inadequate treatment of the emergency on the other. Current textbook guidance tends to be unhelpful in these circumstances. Pethidine is usually regarded as dangerous in combination with MAOIs, but morphine, methadone, and opiates in general are often also included in lists of contra-indicated drugs. Further advice, when given, usually refers to the test dose procedure of Churchill-Davidson (1965), which involves giving small incremental doses of pethidine or morphine over three hours and is hardly suitable in an emergency.

What is insufficiently appreciated is that the MAOI/narcotic interaction has two distinct forms. There is an excitatory form, characterised by sudden agitation, unmanageable behaviour, headache, hyper or hypotension, rigidity, convulsions, hyperpyrexia, and coma, which is thought to be due to central serotonergic over-activity, and a depressive form, consisting of respiratory depression, hypotension, and coma, due to inhibition of hepatic microsomal enzymes by MAOI with accumulation of unmetabolised narcotic. Pethidine and possibly dextromethorphan are the only analgesics which have elicited the excitatory response.

Interaction with pethidine

The first report of pethidine interaction (Mitchell, 1955) concerned a 60-year-old doctor treated for pulmonary tuberculosis with iproniazid. He developed severe muscle twitching, profuse perspiration, hyper-reflexia, and upgoing plantar responses within 20 minutes of treatment with pethidine (100 mg, i.m.). He recovered and his death a year later was probably unrelated. Iproniazid also had a vogue in the treatment of intractable angina, and three cases were reported of similar sudden deterioration after the additional administration of pethidine (Papp & Benaim, 1958; Shee, 1960). Further reports appeared of seven psychiatric patients on a variety of MAOIs who were given pethidine for surgery, labour pains, severe headache, and backache (Palmer, 1960; Clement & Benazon, 1962; Reid & Jones, 1962; Cocks & Passmore-Rowe, 1962; Denton *et al*, 1962; Taylor, 1962). Six patients had a sudden excitatory reaction; two of these died. The seventh had a gradual depressive response and recovered. Two patients who were treated for hypertension with the MAOI pargyline also received pethidine (Vigram, 1964); one of them quickly became rigid and comatose, and the other one became hypotensive over four hours. Both recovered. One of the few recent reports (Meyer & Halfin, 1981) described a man with coccidioidomycosis who developed 'atypical depression' and was treated with phenelzine. He was also given pethidine for headache, and suddenly became angry, excited, and tearful and made purposeless writhing movements.

On the basis of the results of animal experiments, it has been postulated that the excitatory response is caused by an elevation of 5-hydroxytryptamine (5HT) levels. This follows monoamine oxidase inhibitors (Rogers, 1971) and is potentiated by pethidine, which blocks neuronal uptake of 5HT (Brown & Cass, 1979). Animals pre-treated with inhibitors of 5HT synthesis do not exhibit a rise in cerebral 5HT or the excitatory response (Penn & Rogers, 1971).

Interaction with morphine

In a comprehensive review of MAOI interactions, Stockley (1981) wrote that "well documented, serious, and potentially fatal pethidine/MAOI interactions also cast a shadow over morphine, and resulted in the appearance of morphine in a number of lists and charts of drugs which were said to interact with the MAOIs". However, he found only one case report of a severe morphine/MAOI interaction (Barry, 1979). A woman on tranylcypromine (40 mg/day) underwent a pre-operative test of morphine and became unconscious and hypotensive (but continued to breathe) after receiving morphine (6 mg, i.v.). Neither the weight of the patient nor duration of injection were stated, although the latter appears to have been about ten minutes. This reaction was of a different character to that with pethidine, and the patient became fully conscious and normotensive within two minutes of receiving naloxone intravenously.

An American review (American Pharmaceutical Association, 1976) agreed that there was no evidence for the involvement of narcotic analgesics other than pethidine with MAOIs. Two patients who had severe excitatory reactions to pethidine (one fatal) had previously been given morphine with no adverse effects (Shee, 1960; Palmer, 1960). Brown & Waldron (1962) safely gave morphine (20 mg, i.m.) to five patients who developed severe headaches and retrosternal discomfort while on tranylcypromine. Sargant (1975) knew of some ten cases with no side-effects other than a more prolonged morphine action. Morphine has thus been recommended as the narcotic analgesic of choice in the presence of MAOI administration (American Pharmaceutical Association, 1976).

Interactions with other narcotics

Dextromethorphan, like pethidine, blocks neuronal 5HT uptake. Rivers & Homer (1970) reported a fatal interaction. A 26-year-old woman receiving phenelzine (15 mg q.d.s.) for depression consumed 60 ml of a cough mixture containing dextromethorphan. Within an hour she became unconscious, rigid, and severely hypotensive with fixed dilated pupils. Her body temperature was 42°C. She died despite attempted resuscitation. Dextromethorphan should be considered as dangerous as pethidine and is absolutely contra-indicated.

There is little information about interactions with other narcotics. Methadone has been given concurrently with tranylcypromine, both at 30 mg/day, for three months without mishap in a drug addict who developed depression while on a withdrawal programme (Mendelson, 1979).

Pentazocine has been studied in animals in which interactions with MAOIs have occurred (Rogers & Thornton, 1969), but it is not clear if this occurs in man. Relevant clinical and experimental reports regarding the recently-introduced analgesics buprenorphine, meptazinol, and alfentanil, together with fentanyl and phenoperidine (which are used exclusively in anaesthetics), are scanty. All of these narcotics are best avoided in the presence of an MAOI.

Management

Morphine does not block neuronal 5HT uptake, but its narcotic effects may be potentiated in the presence of an MAOI because of the inhibition of hepatic microsomal enzymes. In an emergency, when pain relief is required immediately, small doses of morphine may be given with caution, intravenously, and carefully titrated against clinical response. Should a depressive reaction occur, treatment is primarily supportive. Naloxone may reverse respiratory depression (Barry, 1979), but assisted ventilation might also be necessary. If conservative methods for the treatment of hypotension fail, noradrenaline is the most reliable vasopressor. Indirectly acting sympathomimetics (such as metaraminol), which act by releasing endogenous noradrenaline, risk provoking a hypertensive overshoot and should not be used.

Acknowledgement

We would like to thank Dr T. A. Kerr for his helpful advice.

Clomipramine, Tryptophan and Lithium in Combination for Resistant Endogenous Depression: Seven Case Studies

A. S. HALE, A. W. PROCTER and P. K. BRIDGES

Seven patients suffering from severe endogenous depression who had proven resistant to lengthy trials of treatment with tricyclic and other antidepressants are described. Their successful treatment with a combination of clomipramine, L-tryptophan and lithium is discussed in the context of other strategies for the treatment of resistant depression.

About one-third of patients presenting with a major depressive illness fail to respond to the usual doses of tricyclic antidepressants (Klein *et al*, 1969). A variety of strategies have been suggested for the management of these cases, which have included simply increasing the dose. Many patients with resistant depression respond when the dose is increased to the 200–300 mg/day range (Kotin *et al*, 1973; Quitkin, 1985; Schaztzberg *et al*, 1983). Schuckit & Feighner (1972) and Nelson *et al* (1982) report that some patients seem to require doses in excess of 400 mg/day before a response is seen. Quitkin *et al* (1984) discussed the length of such medication trials, and concluded that a tricyclic must be given in adequate doses for at least six weeks before it may be considered to have failed.

Even with high doses given for an adequate period of time there remains a group of depressed patients with endogenous features who fail to respond to tricyclics alone. The addition of lithium to a tricyclic in non-responders has been demonstrated to produce rapid remission in some cases (Lingjaerd *et al*, 1974; de Montigny *et al*, 1983; Heninger *et al*, 1983; Schrader & Levien, 1985). Similarly, the addition of the serotonin precursor amino-acid, tryptophan, has been shown to potentiate the effect of tricyclic antidepressants (Shaw *et al*, 1975; D'Elia *et al*, 1978; Chouinard *et al*, 1979; Thompson *et al*, 1982). The combination of lithium and tryptophan has also been reported to be more effective than either drug separately (Chouinard *et al*, 1979; Worrall *et al*, 1979; Brewerton & Reus, 1983) although there is little evidence for the antidepressant efficacy of tryptophan alone (Burns & Mendels, 1979; Tissot & Shafner, 1980).

The monoamine oxidase inhibitors (MAOIs) may have a unique role in the treatment of some cases of resistant depression (Quitkin *et al*, 1979). Various authors have advocated the cautious use of combined tricyclic and MAOI antidepressants (Sargant, 1963; Ayd, 1966; Sethna, 1974; Goldberg & Thornton, 1978), but Razani *et al* (1983) compared separate high dose tricyclic and MAOI regimens with a combination, albeit in lower doses, and found that the combination did not prove more effective than either drug alone, although there was no higher risk of side-effects.

Bridges (1983) described preliminary experience with the combination of lithium, tryptophan and tricyclics (in particular clomipramine) in resistant depression, following reports by Eccleston (1981) and Shaw (1983). A similar regimen using an MAOI instead of a tricyclic has recently been reported by Barker & Eccleston (1984). We have used clomipramine rather than an MAOI because the side-effects of the tricyclics are generally less potentially dangerous, especially in higher doses. We report further clinical experience with the clomipramine combination, illustrated by seven cases.

Case studies

Case 1

Mrs J. N. is 60 years old, with a definite family history of affective disorder. Her mother suffered from recurrent depression and had frequent psychiatric admissions. A brother died by suicide, and another brother and a nephew have had hypomanic episodes requiring admission. Mrs N had a normal early development. She left school at the age of 14, and was employed in full-time factory work both before and after her marriage at the age of 36. She continued to work until her first admission to hospital for depression, aged 54. Her only son was delivered by caesarian section when she was 40, with no psychiatric complications.

Her psychiatric illness began fourteen months after her husband died from a brain tumour, when she was 53. She had some social difficulties immediately after his death but generally coped well, looking after her son, then aged 13, and continuing with part-time work. Following a short coryzal illness she gradually became increasingly depressed, with psychomotor retardation, diminished appetite, poor sleep and frequent crying. Admission became necessary; at this time she was not noted to be suicidal or deluded, and had intact cognitive functioning.

She was initially treated with nortriptyline (150 mg/day) for two months. Her condition continued to deteriorate – she became confused and disorientated, and developed memory impairment, a presentation which was increasingly suggestive of a cerebral organic pathology. Investigations, including a computerised tomography scan and lumbar puncture, were normal. Nortriptyline was stopped and she was given a course of ECT (11 treatments over six weeks), with little benefit.

Over the next three years she remained in hospital, wandering about the ward entirely mute and self-absorbed, and was quite unable to look after herself. She was doubly incontinent, and would remain in a soiled bed until prompted to rise. She ate voraciously with her fingers, sometimes on inappropriate foods such as a quarter pound of butter. She would often openly masturbate and remove her clothes in public.

Further unsuccesful attempts at treatment included amitriptyline (150 mg/day) for six weeks, mianserin (60 mg/day) for one year, isocarboxazid (30 mg/day) for eight weeks, and intramuscular flupenthixol decanoate (up to a maximum of 100 mg/week). A further course of bilateral ECT (9 treatments) was given, without benefit, while she was taking a combination of mianserin (60 mg/day) with oral flupenthixol (3 mg/day).

A number of psychological factors were thought to be important in the early stages of her illness, including the grief following the death of her husband and her son's disapproval of a liaison the patient later had with a neighbour. She was also thought by some to demonstrate 'learned helplessness'. Accordingly, family therapy and behavioural programmes were attempted, with no success.

During these three years in hospital she remained mute and in a state of virtual stupor. She was then referred to the Geoffrey Knight Psychosurgical Unit for Affective Disorders at the Brook Hospital in London. There she received a full neuropsychiatric assessment with detailed physical investigations, but again there were no abnormal findings. Taking this into account, together with the strong family history and the initial presentation of an unambiguous depressive picture, the Unit recommended a trial of high dose and then combined antidepressants. She was therefore given clomipramine (up to 225 mg/day, the maximum dose tolerated without hypotension), and later also tryptophan (2 g at night). This regimen produced no benefit, so after four weeks lithium carbonate, increasing to 600 mg daily, was added.

At a ward round three weeks after lithium was started, she casually replied 'not too bad' when asked how she felt, the first comprehensible words that she had spoken for at least three years. Thereafter, her recovery was uncomplicated and quite rapid. She became sociable, involved herself in ward activities, and reported no depression. She remained on this medication and, following rehabilitation, was discharged back to her own home four months after she resumed speaking.

Mrs N. formed a relationship with a male patient during the last weeks of her stay in hospital, and on his discharge he went to live with her. However, there was an argument about money and he attacked her, causing severe lacerations. This necessitated surgical treatment which was associated with her medication being stopped apart from the lithium. She subsequently resumed attendance at a psychiatric day hospital and remained well, so the clomipramine and tryptophan were not restarted.

Three months after her injury, her psychiatric condition deteriorated. She again became confused, untidy and took her lithium only erratically. She was readmitted to hospital, where she again wandered about, and sometimes lost herself in the hospital. She neglected herself and became increasingly withdrawn. Her condition again came to suggest an organic brain syndrome, but investigations were all negative. Clomipramine (225 mg/daily) was then added to the lithium, together with tryptophan (2 g at night). Within three weeks she was well enough to leave hospital. To date she has remained well on these three drugs for four years, still at the original doses. She is now a chatty, extravert, cheerful woman with many interests. She lives independently at home, attends a day centre and goes to a sea-side holiday camp by herself twice a year.

Comment

High-dose clomipramine with tryptophan was not effective on this patient. However, these two drugs, with the subsequent addition of lithium, resulted in rapid recovery after a totally refractory illness lasting three years. When the medication was reduced to lithium only, because of surgical treatment, there was a relapse to the patient's earlier stuperose psychiatric state; lithium alone was not effective, therefore. The addition of clomipramine and tryptophan to the lithium again resulted in recovery, and these three drugs have kept the patient entirely well for the past four years. Reviewing this patient's three years of treatment during her admission, it seems that the triple drug combination succeeded with an illness which did not respond to ECT. However, one could only be certain of this if these drugs had followed soon after ECT had been ineffective.

Case 2

Mrs P. B. is a 54 year-old woman with a 23 year history of recurrent endogenous depression. She had previously been cheerful, well-adjusted and happily married. There is no family history of affective disorder.

She was first admitted to hospital, aged 31 years, with depression; she received no physical treatments and discharged herself after three months. She was readmitted ten years later with depression following redundancy, and she made a slow recovery after ten treatments of ECT. Two years afterwards she again became depressed, and recovered with dothiepin (100 mg/day) after four weeks. She remained well for a further two years, when there was another episode of depression and she took an overdose of her benzodiazepine night sedation. She then failed to respond to amitriptyline (150 mg/day) and to a further course of ECT, and she continued to express suicidal intent.

She was referred to the Geoffrey Knight Unit, and a stereotactic subcaudate tractotomy was performed which produced remission for one year. She then again became depressed, but responded to a combination of dothiepin (50 mg/day) and lithium carbonate (800 mg/day). On this regimen she remained well for nine months, but she then relapsed into a state of agitated depression. She responded slowly to a combination of trimipramine (50 mg/day) and phenelzine (45 mg/day), and on this regimen remained well for two years.

Nine months after this, combination therapy was discontinued. She again relapsed and showed no reponse to its being recommenced, nor to a combination of Parstelin (4 tabs daily) with oral flupenthixol (3 mg/day). Cognitive therapy was tried, to no effect. Clomipramine (100 mg/day) was then given without improvement until tryptophan (1 g/day) was added during the fourth week, following which there was a slow but steady return to normal functioning. The patient remained well on this regimen for two years, but relapsed soon after it was stopped. She then showed a clinical picture of severe retarded depression with suicidal ideas.

Clomipramine was restarted, the dose increasing to 150 mg/day. Above this dose postural hypotension occurred. There was no response after eight weeks and lithium was added, producing a blood level of 0.9 mmol/dm^3. A partial response was seen after two weeks, but complaints of early morning wakening, diurnal variation of mood and lethargy continued. Clomipramine was now tolerated up to 200 mg/day but there was no improvement after a further six weeks. Tryptophan (2 g/day) was added, and the following week the patient attended again with her husband, who volunteered that she was completely well: "back to her old self for the first time in twenty years". She has remained completely well for eighteen months with no change in medication.

This case suggests that L-tryptophan can be essential for the maximum benefit from clomipramine and lithium.

Case 3

Mrs J. C. is a 32 year-old mother of three who presented with a third episode of depression, biological features having been evident on each occasion. She had complete remissions after treatment with dothiepin (150 mg/day) for each previous illness, remaining completely free of symptoms for seven years after the first and two years after the second illness. She has a strong family history of depression, bipolar on the father's side and unipolar from her mother's family. Her three brothers are all affected. Her younger brothers are dizygotic twins; one shows bipolar and the other unipolar symptom patterns. The patient herself has not shown evidence of bipolarity.

Mrs J. C. initially received psychotherapy for the most recent episode of depression, which began with free-floating anxiety and somatic complaints, but she was referred for physical treatments once early morning waking, morning worsening of mood and weight loss become apparent. She received the following medication with little success: dothiepin (200 mg/day) for eight weeks; amitriptyline (200 mg/day) for six weeks; and clomipramine (250 mg/day) and tryptophan (2 g/day) for six weeks.

The patient was initially unwilling to take lithium, and the additon of carbamazepine (300 mg/day) produced little improvement. The patient rejected admission to hospital for ECT, but eventually agreed to a trial of lithium. She was symptom-free within three weeks of achieving a plasma lithium of 0.8 mmol/dm^3 on a dose of 800 mg/day and has remained well over the subsequent eighteen months while also continuing the clomipramine and tryptophan. There was an attempt to reduce the dose of clomipramine, but early morning waking recurred; this cleared up when the medication was returned to the original level.

Carbamazepine, at least at 300 mg/day, thus did not prove to be an effective substitute for lithium in this case.

Case 4

Mrs J. S. P. is a 42 year-old mother of two, referred following the sudden onset of severe endogenous depression with occasional panic attacks. She had suffered an episode with similar symptoms during a pregnancy nineteen years earlier, but this had cleared at the time of the delivery and she had remained well since. There is no family history of affective illness. She had failed to respond to the following medication regimens: mianserin (30 mg/day) for three weeks; dothiepin (200 mg/day) for eight weeks; dothiepin (200 mg/day) and tryptophan (2 g/day) for three weeks.

Drowsiness prevented a further increase in the dose of dothiepin, and the tricyclic was changed to clomipramine, up to a dose of 250 mg/day. This produced some improvements, but significant symptoms remained after six weeks. Lithium carbonate was then added, giving a blood level of 0.65 mmol/dm^3 on a dose of 400 mg b.d. Significant improvement was seen within a week; complete remission was achieved after four weeks, and continues to date (over one year later).

Case 5

Mrs A. B. is a 49 year-old woman with a unipolar depressive illness which began at the age of 44, shortly after a hysterectomy and salpingo-oöphorectomy for endometriosis. Her father had committed suicide while depressed.

She has had two episodes of depression, each requiring hospital admission following self-mutilation and suicide attempts. On her first admission she recovered with ECT (12 treatments) and phenelzine (45 mg/day) with trimipramine (50 mg/day). Although she remained on this combination she rapidly relapsed and was readmitted following a serious suicide attempt six months later.

Her treatment during this second admission included: phenelzine (45 mg/day) and trimipramine (50 mg/day) for one month; imipramine (150 mg/day) for one month; imipramine (150 mg/day) and lithium (600 mg/day) for two months. She then received clomipramine (150 mg/day), tryptophan (2 g/day) and lithium (600 mg/day). She began to improve within six weeks of starting this regimen, and so far has remained fully recovered for eighteen months.

Imipramine and lithium were not effective, but clomipramine, tryptophan and lithium were. This could reflect a possible greater potency for clomipramine compared with imipramine, or the improvement may be related more to the addition of tryptophan.

Case 6

Mr B. P. is a 40 year-old man who had suffered from a single episode of depression varying continuously for five years. He had no previous psychiatric history and no family history of affective illness.

He was admitted to hospital at the age of 36 with severe depression and depressive delusions. He responded partially to ECT (6 treatments) but remained anxious, and he still expressed ideas of worthlessness. He then received the following medication: clomipramine (150 mg/day) for three months; clomipramine (75 mg/day) for two months; imipramine (200 mg/day). Imipramine produced a partial recovery such that he was able to be discharged and resume part-time work. He remained very anxious and depressed, and he received weekly interpretive psychotherapy for two years with little change in this condition.

He was readmitted to hospital, as he had not improved, and he received the following treatment: phenelzine (60 mg/day) for two months; ECT (6 treatments) with little benefit; imipramine (225 mg/day) for four weeks; imipramine (225 mg/day) and tryptophan (1.5 g/day) for four weeks. He was then given clomipramine (300 mg/day) and tryptophan (2 g/day) for four weeks. As there was little improvement, lithium (400 mg/day) was added. Within two weeks he made a full recovery, and he remained well on this triple medication for over a year. Since then he has continued well for another year on clomipramine only.

Case 7

Mrs J. S. is a 58-year old woman who has been admitted to hospital six times with unipolar depressive illness which began at the time of her menopause, at the age of 48. She has no family history of affective illness. Her first five episodes of depression responded rapidly to antidepressants of ECT, and she completely recovered each time.

The last episode of depression began when she was 51; she received the following treatment over the next six years with little effect: amitriptyline (175 mg/day) for two months; amitriptyline (100 mg/day) and imipramine (75 mg/day) for two months; nortriptyline (150 mg/day) for two months; clomipramine (75 mg/day) for three months; phenelzine (60 mg/day) for four weeks; ECT (8 treatments) produced a little improvement, but was not repeated; nomifensine (150 mg/day) for three months; phenelzine (60 mg/day) for three months; mianserin (30 mg/day) for two months; clomipramine (100 mg/day) for three months.

The clomipramine was then increased to 150 mg/day and tryptophan (1.5 mg/day) added. Lithium, increasing to 800 mg/day, was later also prescribed. Within six weeks of receiving these three drugs the patient showed a marked improvement and has remained well on this combination for four years.

Discussion

All seven of the cases reported received lengthy trials of tricyclic and other antidepressants. The doses in Quitkin *et al*'s (1979, 1984) studies varied between 200–300 mg/day, levels considerably higher than are usually used in Britain; Paykel (1979) has recommended that doses should be pushed to the point where side-effects are definite and moderate but still tolerable. In the cases reported this was usually at the onset of persistent postural hypotension, as discussed by Eccleston (1981). In each case several tricyclics had been used, the different side-effects permitting higher doses with some than with others. Management then progressed variously through a variety of other types of antidepressants, combination regimens and then ECT. Two patients received the reputedly hazardous combination of a tricyclic and an MAOI, in both cases with some short-lived benefit. In both, phenelzine and trimipramine was used, as recommended by Young *et al* (1979). Neither these authors, nor studies by White *et al* (1980) or Razani *et al* (1983), found such a combination superior to either drug used alone in adequate doses. Davidson *et al* (1978) compared five weeks of combined treatment with phenelzine and amitriptyline with ECT in resistant depressives. Although the study may be criticised for the low drug doses used, ECT emerged as clearly superior. However, ECT also failed in the cases we have reported.

It may thus be argued that these cases illustrate the unique efficacy of the triple combination of lithium, clomipramine and tryptophan in treating a small group of patients with endogenous depression resistant to many other forms of treatment, and that a trial of this combination should be carried out for apparently intractable cases, because patients might otherwise be condemned to chronic illness. It seems clear that the combination should be tried before a referral for psychosurgery.

There remains uncertainty as to whether the triple combination with clomipramine is more or less potent than with an MAOI instead. Price *et al* (1985) found tranylcypromine and lithium to be effective with a group of patients whose illnesses were resistant to a tricyclic and lithium, and the literature suggests that tryptophan potentiation alone is more convincing with monoamine oxidase inhibitors than with tricyclic compounds (Paykel & Hale, 1986).

Suicide in Scottish Prisons

S. A. BACKETT

A consecutive series of prison suicides in Scotland between 1970 and 1982 was examined. The initial phase of imprisonment was found to be the most vulnerable stage of confinement, with almost two-thirds of the deaths having taken place within the first month. A disproportionately high number were found to be on remand. A history of some form of psychiatric involvement was common, and a third of the group had received previous psychiatric in-patient treatment. In contrast to results from general population studies, there was little evidence to link suicide with a history of depressive illness. A record of problems with either alcohol or drug dependence was found in almost half the cases. The importance of general measures designed to reduce stress and promote coping mechanisms is emphasised.

Considerable concern has been expressed about the number of suicides and parasuicides which take place in prison. There is disquiet that such an event could take place in an environment in which there is a high level of surveillance, and there is a possibility that the prison regime itself may be seen to be instrumental in the process. While few would deny that imprisonment is an unpleasant experience, society accepts responsibility for it in the belief that it will deter future criminal activity. However, the punitive aspect becomes unacceptable if it is thought to be a causal factor in a prisoner's death.

In 1982 the suicide of a young man in a remand centre near London was followed by an inquest verdict which described a 'lack of care' on the part of the prison department. This was the stimulus for the newly formed Inspectorate of Prisons to undertake both an Inquiry into this death and a more general study of the adequacy of arrangements for the prevention of suicide. The report (Home Office, 1984) considered the prevention procedure and summarised the views of a number of interested bodies. Examination of a sample of suicides showed that about two-thirds of them were regarded as having psychiatric problems, with a smaller proportion (not specified) having been patients in psychiatric hospitals. This supports the earlier finding by Topp (1979), who also examined prison suicides in England and Wales. He found that, while in custody, 69% had seen doctors for complaints with a psychiatric connection and 39% were receiving treatment as a consequence. Despite this, the risk of suicide had been recognised in only 15% of the deaths. The Inspectorate of Prisons acknowledged the importance of general measures to reduce suicide, at the same time emphasising the central role that the prison medical officer should have in 'individual prevention'. The medical nature of the task resulted from an understanding that suicide was often associated with mental illness, alcoholism, and drug abuse, and that it required a doctor to identify these conditions and recommend treatment.

A more recent report (Scottish Home and Health Department, 1985) reviewed the suicide precautions in the Detention Centre and Young Offenders Institution at Glenochil in Scotland. This review followed a series of five deaths which had occurred between 1981 and 1985 and which had been the source of increasing public alarm. Recognising the vulnerability of some of the young offenders, many of the recommendations made and provisionally accepted by the Secretary of State could be considered as general measures designed to make the environment more humane and caring.

Problems are encountered when international comparisons are made. Tuskan & Thase (1983) illustrated this when they drew attention to the wide discrepancies that exist between prison suicide rates in different countries. Variations in reporting methods and inmate populations have been suggested to explain these differences.

The United States Bureau of Prisons administers 35 different forms of penal facility, ranging from maximum security penitentiaries to community treatment centres. County jails are the most widely used form of confinement and are the source of the majority of studies into prison suicides (Smialek & Spitz, 1978; Fawcett & Marrs, 1973; Danto, 1973; Helig, 1973). Even these jails differ from one county to the next, which further complicates comparisons either between them or with state or federal facilities. The studies themselves have varied considerably, both in size and objectivity. While some have defined what they consider to be the characteristics of the suicidal inmate, others have demonstrated that these descriptions are not specific enough to accurately identify the individual and intervene effectively. In this respect it is unfortunate that the most detailed and comprehensive study in this area examined suicide in four maximum security penitentiaries in Canada (Burtch & Ericson, 1979); while data presented in this study are impressive by comparison, it is doubtful that consideration of such a specialised form of imprisonment can contribute to our understanding of suicide in other, more widely used penal institutions.

The present study set out to describe the characteristics of a group of prisoners who committed suicide. In view of the reported association between mental illness and suicide in the general population, it was of particular interest to consider the psychiatric contact, and where possible the diagnoses, of a group of prison suicides.

Method

This study examined a consecutive series of deaths classified as suicide in the Annual Report on Scottish Prisons. In Scotland this process of classification starts with the notification of all deaths which have taken place in custody to the Procurator Fiscal. A report is then sent to the Crown Counsel, who act on behalf of the Lord Advocate and decide which of these deaths will proceed to a Fatal Accident Inquiry. Having heard the evidence the Sheriff, who presides over this Inquiry, is asked to give an opinion on the cause of death. Over the years there has been some inconsistency in these determinations: of those deaths subsequently classified in the Annual Report as suicide there have been some in which a specific reference had been made in the Enquiry that the death was due to suicide; others have been less specific, but have resulted in the same classification.

The Scottish Home and Health Department made available, where possible, the prison records, medical files and Fatal Accident Enquiry reports on each of these deaths. In addition, the Information Services Division of the Scottish Health Service provided data on those individuals who had received in-patient treatment in psychiatric hospitals in Scotland. No corresponding information was available for those who may have had in-patient treatment outside Scotland.

In common with other studies (Fawcett & Marrs, 1973; Esparza, 1973) there were many instances in which the files were not complete. When information on areas of social or psychological importance was recorded both the quantity and quality varied considerably, and many items may have been under-reported.

Suicide rate

The estimation of the suicide rate in a changing population, as found in prisons, requires modification before it can be compared to the rate in the general population. Such a situation has been described for in-patients in a psychiatric hospital (Copas & Robin, 1982). Unfortunately the relevant data necessary to make a similar adjustment for this study were not available. In common with other studies (Topp, 1979; Home Office, 1984) the rate was calculated using the mean daily average prison population for the period in question.

Results

General features

Between 1970 and 1982 there were a total of 33 deaths in Scottish prisons recorded as suicide. All were male prisoners. Suicide was the single largest cause of death, and accounted for 37% of the total. Using the mean daily average prison population (1970–1982), the suicide rate was found to be 51.8 deaths per 100 000 per year. The ages ranged from 14 to 59 years, with a mean age of 28.6 years. Eighteen were single, nine married, and six divorced or separated. Eleven of the group were 'under observation' at the time of their death, with four of these having been identified specifically as a suicide risk.

The early phase of imprisonment appeared to be the most vulnerable stage of confinement. Four deaths occurred in the first 24 hours, thirteen within the first week, and twenty in the first month. Two deaths took place within days of the prisoner's intended release. At the time of death fourteen had been sentenced and nineteen were on remand; of the latter group approximately two-thirds were untried, while the remainder were awaiting sentence or further reports prior to sentence. During the period under consideration the percentage of the total prison population classified as 'on remand' varied between 12.2% and 16.9%, with a mean of 14.1%.

Previous criminal involvement was common. Twenty-nine had a criminal history and 24 had experience of imprisonment. Of those that had been convicted, the majority were serving short sentences for non-violent crimes such as theft. The longest sentence being served was four years.

Psychiatric history

Fifteen members of the group had a record of a previous parasuicidal episode, and in half the cases of two or more. Thirteen had given some indication of suicidal intent in the period immediately before the death. This involved self-inflicted injury in seven cases; in the remaining six cases there was some verbal communication, either to a fellow inmate or to a Prison Officer.

Twenty had a history of psychiatric contact, and for seven this had been within the month prior to the suicide (in some instances this was for the purpose of a psychiatric report). During this period there was only one recorded case in which a depressive illness had been identified and treatment commenced.

Eleven were identified as having received in-patient treatment in psychiatric hospitals in Scotland before their imprisonment. These eleven cases accounted for a total of twenty-four separate admissions (Table I). Depressive disorder had been diagnosed in only two instances.

TABLE I
Psychiatric diagnoses of those prisoners who had received in-patient psychiatric treatment

Case no.	*ICD–9*[1]	*Discharge diagnosis*	*No. of admissions*
1	311.9	Depressive disorder (not elsewhere classified)	1
	307.9	Special symptoms or syndromes (unspecified)	1
2	295.9	Schizophrenia (unspecified)	2
	303.2	Alcohol dependence syndrome	1
3	300.4	Neurotic depression	1
4	301.9	Personality disorder (unspecified)	2
	301.7	Personality disorder (sociopathic)	1
5	295.9	Schizophrenia (unspecified)	2
6	303.9	Alcohol dependence syndrome	3
	301.7	Personality disorder (sociopathic)	1[2]
7	301.7	Personality disorder (sociopathic)	1[2]
	301.6	Personality disorder (asthenic)	1[2]
	304.1	Drug dependence (barbiturate)	1[2]
8	304.9	Drug dependence (unspecified)	1
	303.9	Alcohol dependence syndrome	1

1. Diagnosis classification according to the International Classification of Diseases (World Health Organization, 1978).
2. Self-inflicted injury on admission.

It had been documented in the records of fifteen of the group that they had either an alcohol or drug-related problem. While the majority of deaths for the group as a whole occurred during the initial period of imprisonment, this was particularly apparent for those prisoners with these problems: nine of these fifteen deaths took place within the first week. Examination of the medical files of this subgroup provided evidence which suggested that a third of them were experiencing withdrawal symptoms at the time of, or immediately before, the suicide.

Discussion

Any conclusions that can be drawn from these data must be qualified by the fact that the study considered only those deaths which had been officially classified as suicide. Apart from noting the numbers involved, no attempt was made to examine critically the other prison deaths.

Studies by both Robins *et al* (1959) and Barraclough *et al* (1974) have shown that in the general population mental illness can be identified in virtually all suicides. Depressive illness was the most common diagnosis, and a previous history of the same illness was found in almost half the cases. If a similar situation exists for those suicides in prison, it follows that any attempt at prevention should involve the early diagnosis and treatment of this illness.

The suicide group in this study had experienced a considerable amount of psychiatric involvement, with some of this contact taking place in the period immediately preceding the death. In addition, one in three had a history of psychiatric in-patient treatment. There was little evidence that depressive illness at the time of death, or a previous history of this illness, was common; in only one case from the prison records and two from the in-patient group could this diagnosis be found. This suggests that factors other than depressive illness may be important in those suicides which take place in prison.

An alternative approach is to view these deaths as the result of varying degrees of stress rather than formal illness. Support for such a situation can be found in the study by Gunn *et al*, (1978), which examined the prevalence of psychiatric disorder in prison. They examined a sample of prisoners with a combination of psychiatric interviews and questionnaires. The results showed that a high degree of disturbance and psychological discomfort was experienced by the prison population as a whole. The level of this distress appeared to be maximal during the initial phase of imprisonment and, although remaining comparatively high, diminished with the passage of time. This change was attributed to a subsequent adjustment to prison life.

Prison suicides follow a similar pattern. This study, in common with many others, found that the majority of deaths occurred shortly after admission to prison. This is the time when the stress factors are most numerous and when the prisoner faces the greatest amount of uncertainty. It could be argued that this results in a continuum of distress, rather than a specific illness with a recognisable constellation of symptoms. In this situation the suicide may take place if, and when, a critical threshold is exceeded. The threshold varies, and is dependent on a balance between the factors themselves and the individual's resources to cope with them. One of the stress factors identified by this study was the symptoms associated with withdrawal from either drugs or alcohol.

Coping mechanisms which might be used by the prisoner have recently been discussed in a review by Coid (1984). He described the way the prison subculture may facilitate the prisoner's adjustment to prison life. In the first place, membership of this group may itself lead to a reduction in the feeling of isolation. In addition, by standing in opposition to the prison staff and management, and by the creation of an 'us' and 'them' situation, the prisoner may regain a feeling of control. This in turn may restore some of his self-esteem and promote a sense of autonomy. The problems arise because acceptance to such a group is neither an immediate process nor equally available to all prisoners. Some will be denied membership owing to the nature of their offence, or aspects of their mental state or personality. As a result of this exclusion they may remain in a vulnerable state. The combination of the clustering of stress factors, and the inadequately developed coping mechanisms, may help to explain the timing of the suicides and the period of adjustment noted by Gunn *et al* (1978).

Finally, it is important to remember that suicides, whether they take place in or outside prison, are rare events, and that it is difficult to predict such an event. This study supports the suggestion that the suicidal prisoner presents with few characteristics which would assist the process of identification. While alcohol and drug related problems may be associated, an identifiable depressive illness does not commonly precede the suicide.

When considering the prevention of suicide in prison it may be more appropriate to emphasise general measures designed to reduce stress and promote coping mechanisms, rather than concentrate on the recognition of the suicidal prisoner. The prison Medical Officer undoubtedly has an important role to play in this. Nevertheless, he will require support from many different areas if the necessary changes are to be made.

Acknowledgements

I would like to thank the staff of the Prisons Division, Scottish Office, Dr Ian Kemp of the Information Services Division of the Scottish Health Service, and Professor N. Kreitman from the MRC Unit for Epidemiological studies in Psychiatry, Edinburgh.

Reality Orientation and Reminiscence Therapy

A Controlled Cross-over Study of Elderly Confused People

SHEILA BAINES, PETER SAXBY and KAREN EHLERT

We compared reality orientation with reminiscence therapy for elderly people in a large residential home, using a controlled cross-over design. Both kinds of therapy group were enjoyed by both staff and residents, and enabled staff to get to know moderately and severely confused residents. The group that received reality orientation followed by reminiscence therapy showed improvement in cognitive and behavioural measures which was not found in the other two groups. It may be important to use reality orientation techniques with confused residents before involving them in a reminiscence group.

In spite of the predominantly negative attitude of Western culture to old age (Butler, 1974; Stearns, 1977; Blythe, 1979; Emery, 1981; Thomas 1981) and the many physical, social and psychological difficulties encountered by this age group, the majority of elderly people appear to live busy, meaningful lives. Like younger people, many live relatively independently in the community; either alone, with spouses, or with families or friends. Less than 10% show the kinds of confused behaviour associated with dementia, i.e. disorientation, withdrawal, bizarre habits, or distressed feelings; and even when they do, the majority remain at home or spend only a limited time in hospital (Kay *et al,* 1964; Kay *et al,* 1970; Bergman *et al,* 1978).

Nevertheless, a significant number of elderly people live permanently in residential homes or hospitals, for various reasons. In these populations the proportion of confused residents is much higher than in the community. Recently it has been found that approximately one-third of residents in non-specialist local-authority homes could be described as moderately or severely confused (Evans *et al,* 1981). These residents tend to be dependent and withdrawn and to take little part in the social and recreational activities provided by the home.

For many years it was felt that nothing could be done to improve the quality of life for these residents, apart from providing good physical care. The situation changed, however, when researchers and other workers in the caring professions began to recognise that the environment could exert a powerful effect on behaviour, even when there was a physical basis for that behaviour. They found that elderly confused people could respond favourably to social and behavioural therapy (Taulbee & Folsom, 1966; Folsom, 1968; Burnside, 1976; Citrin & Dixon, 1977; Miller, 1977; Hennessey, 1978). The most widely accepted and researched technique up to now has been *reality orientation* (RO) (Greene *et al,* 1979; Holden & Woods, 1982).

More recently another technique called *reminiscence therapy,* which is based partly on one of the components of RO, has been gaining popularity (Ebersole, 1978; Norris, 1981; Lesser *et al,* 1981). However, there appear to have been no major studies of the effects of reminiscence therapy on the elderly confused.

Both reality orientation and reminiscence therapy aim to help the elderly confused towards three objectives: relearning conversational skills, co-operating in social activities, and taking an interest in the world. Reality orientation aims also to restimulate basic orientation.

The contents of reality orientation programmes vary but all are based on the idea that certain kinds of basic orientating information are essential if the confused person is to function at a reasonable level. Emphasis is therefore placed on teaching the day, date, weather, time and use of names (Barnes, 1974; Holden & Sinebruchow, 1978; Taulbee, 1978; Greene *et al,* 1979; Woods, 1979). Reality orientation, conducted individually or in groups, can lead to a significant reduction in disorientation (Harris & Ivory, 1976; Greene *et al,* 1979; Jeffery, 1981, 1982; Merchant & Saxby, 1981; Powell-Proctor & Miller, 1982) and an improvement in communication for those who are mildly or moderately confused (Brook *et al,* 1975; Holden & Woods, 1982). However, most improvement appears to be fairly specific to verbal reorientation and there appears to be little measurable behaviour change (Powell-Proctor & Miller, 1982). This could be either (*a*) because specific intervention techniques lead only to specific and not generalised results (Hanley *et al*, 1981); or (*b*) because the measures used are not sensitive enough to detect changes in behaviour.

If reality orientation is successful only in improving certain kinds of basic knowledge, it is important to know whether or not this knowledge really is essential for the individuals concerned. Even when the gain in information is accompanied by a more generalised improvement in well-being and an accompanying improvement in staff morale, it may well be that the important elements of an RO programme are not the orientating information but the stimulating influence of the social group. Woods (1979) found that residents in an RO group improved more on tests of information, orientation and various aspects of memory than similar residents in an unstructured social-therapy control-group. It is possible that these improvements were brought about because the RO groups were structured: the actual content of the RO programme may not have been important. Rating-scale assessments of the residents' functioning in the home showed no differential effect; but the staff running the groups felt that the social therapy was more effective and that these groups were easier to lead. This suggests that the staff, and probably the residents, found the social groups more enjoyable. If one of our aims in running groups is to improve the quality of institutional life, it is important that both staff and residents find the experience generally enjoyable or worthwhile; and since the gains achieved during a formal RO programme dissipate quickly once the programme has ceased (Miller, 1977; Feier & Leight, 1981; Powell-Proctor & Miller, 1982), it is important that staff and residents find the experience rewarding so that groups continue and perhaps diversify into different kinds of specialist groups.

This paper reports on an attempt to find out whether our particular RO programme and reminiscence programme were effective in bringing about cognitive, emotional and behavioural changes in the subjects, and whether the effects of the two programmes could be differentiated. It was hoped also to gain more information about the effects of such programmes upon the staff running the groups, since it has been suggested that the main value of RO may be its positive impact on the staff (Powell-Proctor & Miller, 1982; Hanley *et al.* 1981).

Method

Subjects

Subjects were chosen from the residents of a large (62-place) local authority home for the elderly. Out of 20 residents selected by staff as being confused, three were excluded because of severe communication problems. Of the remainder, 15 obtained scores on the 'Information/Orientation' and 'Mental Ability' portions of the Clifton Assessment Procedures for the Elderly (CAPE) (Pattie & Gilleard, 1979) which suggested moderate-to-severe impairment of cognitive functioning. The two with adequate cognitive functioning were excluded from the study. All 15 confused subjects had sufficient sight and hearing to participate in a small group: these 15 subjects were assessed by an independent psychologist, matched for age and cognitive functioning, and randomly assigned to one of three groups.

Some details of the subjects are summarised in Table I: there were no statistically significant differences between Groups A, B and C. All the subjects had been in the home for some time (mean 3 years 4 months, range 8 months–10 years). Their ages ranged from 72 to 90 (average 81.5), and 14 of the 15 were female. Although the residential home regularly provided activities such as bingo sessions, singing groups and outings, our subjects rarely participated and spent a great deal of time in social isolation.

Design

The 15 subjects were divided into three matched groups of five, designated A, B and C. The subjects in the control

TABLE I

Characteristics of subjects at the beginning of the study. The mean value is given for each matched group of five subjects: there were no statistically significant differences between groups

	Group A	*Group B*	*Group C (controls)*
Age: years	81.4	82.7	80.4
Length of residency: years	3.52	4.6	1.92
Information/orientation score[1]	5.4	5.8	5.9
Mental ability score[1]	6.8	8.2	7.4

[1] Measured by the cognitive assessment scale of CAPE (Pattie & Gilleard, 1979)

group (C) received no treatment. Those in Groups A and B were exposed in turn to both reality orientation sessions and sessions of reminiscence therapy, in a cross-over design of study.

Six members of staff were allocated randomly to one or the other of the experimental groups: three worked throughout with Group A and the other three with Group B. Each group session was run by a member of staff and a research clinical psychologist (SB). Preliminary training for the staff consisted of six hours of introductory talks, videos, discussions and hand-outs.

Procedure

Each group met for half an hour a day at the same time Monday–Friday for two 4-week periods. All sessions were tape-recorded. A comfortable, conventionally furnished sitting room was used. Tea was served at all sessions to help create a social atmosphere.

The *reality orientation* sessions followed the format outlined by Holden & Woods (1982) for the 'standard group'. We used a large board for recording the day, month and weather, as well as writing materials, old and current newspapers, and personal and local photographs from past and present. We also used materials to stimulate all five senses (not just sight and hearing); e.g. substances with a distinctive smell, such as vials of rosewater or sachets of cinnamon; materials with a distinctive feel, e.g. silk or sandpaper; and foods with distinctive taste and texture, like pickles or honey.

The *reminiscence therapy* sessions were based on the format suggested by Andrew Norris (Norris, 1986). We used a set of six audio/slide programmes designed to facilitate reminiscence in the elderly (Help the Aged, 1981), old photographs of local scenes, residents' personal photographs, books, magazines, newspapers and domestic articles.

When reminiscence material was used in the reality-orientation sessions, comparison was always made with the present day. These explicit comparisons were not made in the reminiscence therapy sessions, althoug some residents spontaneously commented on the differences between past and present. Historical accuracy was not deemed to be important during reminiscence therapy, but it *was* during reality orientation.

Subjects in all the groups were told that they were helping in an experiment to find out what techniques could help elderly people who were having problems with their day-to-day memory or past memories.

At the end of each session, each staff member made a subjective assessment (on a 5-point scale) of how much each resident had enjoyed the group that day. Staff not running the groups but working closely with the residents involved were asked to make the same assessment, after observing the subjects' behaviour and chatting informally to them about their day.

Measures

Assessment of staff

Staff members running the groups were interviewd individually using a semi-structured open-ended format, and the interviews were tape-recorded. Staff also completed questionnaires about the perceived effects of reality orientation and reminiscence therapy. This was done three times: before training to run groups; again at the end of Stage I; and again at the end of Stage II (see Fig 1). On each occasion they were also asked to complete a personal information questionnaire for each resident in their group and in the control group, without referring to records. The Personal Information Questionnaire (Hanley, 1982) asks basic questions about the resident's family, former work roles, and past and present hobbies and interests.

Assessment of residents

The following measures were taken before and after each period of group therapy, and again one month after sessions ended (see Fig. 1):

1. The Cognitive Assessment Scale (CAS) of CAPE (Pattie & Gilleard, 1979), excluding the Gibson Spiral Maze, and giving measures of:
   (a) Information/orientation
   (b) Mental ability
2. Life Satisfaction Indices (Gilleard *et al*, 1981).
3. CAPE Behavioural Rating Scale (BRS), (Pattie & Gilleard, 1979).
4. Problem Behaviour Rating Scale (Jeffery, 1981), which assesses (on a 7-point scale) specific behaviour patterns associated with confusion.
5. Holden 5-point Communication Scale (Holden & Woods, 1982).

Measures 1 and 2 were completed by the residents with the aid of an independent psychologist. Measures 3, 4 and 5 were completed by staff who knew the residents well but were not involved with the therapy groups.

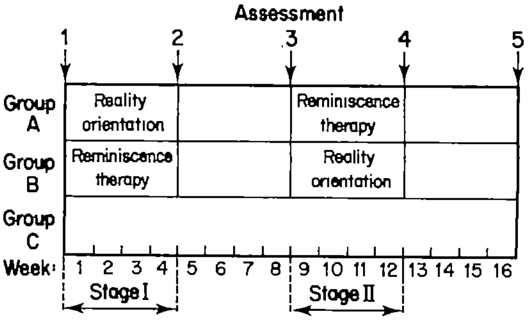

FIG. 1 Design of the study.

Results

End of Stage I

Effects on residents

The results after four weeks of regular sessions are shown in Table II (assessment 2). At this stage, Group A (after four weeks of reality orientation) had improved on measures of information/orientation and communication, and on both

TABLE II

Scores on measures of cognitive ability, emotional state and behaviour, assessed every four weeks throughout the study period. Data represent mean ± s.d. for each group of five subjects. On measures of information/orientation, mental ability and life satisfaction, higher scores represent improvement; on measures of behaviour and communication, lower scores represent improvement

4. Behaviour: CAPE Behavioural Rating Scale (Pattie & Gilleard, 1979)
5. Communication: Holden & Woods (1982)
6. Problem behaviour: Jeffery (1981)
7. Group C, assessment 5: scores for four subjects only, as one died

*Statistically significant difference between groups behaviour scales. The improvement on measure 4 (BRS) was significantly greater than in the other two groups (Kruskal Wallis $P<0.009$, Group A over B and C; Mann Whitney $P<0.008$, Group A over B; Mann Whitney $P<0.009$, Group A over C). Group B (the reminiscence group) showed a slight improvement in life satisfaction compared with the other two groups, but this difference was not significant.

Since it has often been suggested (Miller, 1977; Powell-Proctor & Miller, 1982) that any positive effects of reality orientation disappear rapidly once sessions are discontinued, the residents were tested again a month after the groups ended (Assessment 3). As can be seen from Table II, the improvements shown by the RO group (A) on measures 3, 4 and 5 (BRS, Holden and Problem Behaviour scales) were maintained, but the improvement in information/orientation score was lost. However, both therapy groups did maintain their scores for information/orientation, whereas the no-treatment control group showed a marked decline: this difference from the control group was significant for the reminiscence group (Mann Whitney $P<0.0259$). It is possible that the therapy groups had some positive interaction with the residents in the control group in the experimental period (see below).

Enjoyment of groups by residents

The residents in both groups A and B seemed to enjoy the sessions: their daily attendance record was high (mean 82% for Group A residents, range 41%–100%; mean 86% for Group B residents, range 65%–100%). This regular attendance might be interpreted as compliance to staff encouragement. However, it was exceptionally high, and in marked contrast to their previous behaviour. Reitz & Hawkins (1982) found that less than 50% of the nursing-home residents in their study attended group recreation sessions, even when staff personally invited them to attend.

Although there were fluctuations in individual scores, staff assessment suggested that all the residents had enjoyed the groups (see Table III).

TABLE III

Enjoyment of sessions by residents (assessed by staff). Rating scale from 1 (non-enjoyment) to 5 (maximum enjoyment). No significant difference was found between groups or between types of therapy

Effects on staff

The results from the Personal Information Questionnaire (Table IV) supported the impressions of staff that taking part in group sessions helped them to get to know the individuals in their own groups. Before sessions began, the staff knew very little about the residents in any of the three groups: out of a possible total of 40 items, an average of only 5.33 was known about each resident. By the end of Stage I staff knew much more about the residents in groups A and B: there was no difference in their knowledge between the two therapy groups, but the difference between them and the control group was very large (Kruskal Wallis, $P<0.009$).

All six staff were enthusiastic about the positive effects the sessions had on the residents, although they felt the effects were more marked for the less severely confused. The staff themselves enjoyed taking part in the groups. Five out of six felt that the group experience had helped them to talk more freely to residents on a variety of topics, both outside and inside the group sessions. They also found it easier to allow residents to express their feelings and found that they were no longer avoiding talking to residents about potentially emotive topics.

End of Stage II and follow-up

Effects on residents at end of Stage II

During this stage the treatments were crossed over: Group A residents received four weeks of reminiscence therapy and Group B four weeks of reality orientation. The results are shown in Table II (assessment 4).

Although neither group had met for a month, there was some indication that the previous group experience had affected their behaviour.

Group A residents continued to function as they had done at the end of the previous series of sessions: from the beginning they spoke to one another as well as to staff; they addressed people by name; and they talked spontaneously about current topics of interest in the residential home such as recent illnesses and deaths, and recent or forthcoming outings. They then moved on to the reminiscence topic of the day but continued to compare and contrast past and present.

Group B residents were less willing to use names or discuss day-to-day events and this made it difficult for staff to initiate reality orientation techniques. At first the residents spoke very little to one another and addressed their remarks to the staff. They seemed to remember the room and wanted to talk about their own past experiences, but appeared detached from the other residents. This may explain the drop in information/orientation scores during this period.

TABLE IV

Staff's knowledge of residents: Personal Information Questionnaire scores before and after therapy (maximum possible information = score of 40)

	Scores for individual residents[1]					*Mean*

End of Stage II	3	4	8	6	4	5.0

*Statistically significant difference from control group

[1] Each score represents the pooled knowledge of the three members of staff involved in the relevant group (A or B); pooled knowledge of all six staff for patients in Group C

Nevertheless, by the end of Stage II they were interacting with one another as well as they had been doing at the end of the first therapy period.

Meanwhile, Group A residents again improved their scores on Information/Orientation, Holden and Problem Behaviour scales: compared with Group B, the improvement Information/Orientation scores was significant (Mann Whitney, $P < 0.0413$). These results support our impression that Group A residents had gained a group identity in the reality orientation sessions which helped them benefit from the reminiscence therapy which followed.

Residents in the control group also improved their Information/Orientation scores but not to the pre-therapy level; and there was no steady improvement on the Holden or Behavioural Ratings, with the exception of one resident who shared a room with a Group A resident. The individual scores of just two residents in the control group were largely responsible for the increase in the mean information/orientation score, and each of these two shared a room with a resident in Group B. No other subjects shared rooms with each other, so it would appear that these residents were obtaining some benefit from the attendance of their room-mates at group sessions.

The changes in the life-satisfaction scores showed the same trend as had been seen in the first experimental period: residents in the reminiscence group improved their scores while those in the reality-orientation group decreased theirs and the control group showed little change.

Effects on residents at follow-up

The residents in the three groups were tested again one month after the experimental period had ended. The results are shown in Table II (assessment 5). Although there was a slight decline in their Information/Orientation scores in the follow-up period, Group A maintained most of the improvements gained in the second therapy period. The scores for the other two groups showed little or no change: but on the Information/Orientation measure Group B residents maintained the scores attained at the end of the therapy period while the average scores of Group C residents declined.

Enjoyment of groups by residents

As in Stage I, although day-to-day fluctuations in individuals' mood and physical state produced some variation in enjoyment, the generally high level of attendance suggested that on the whole residents enjoyed attending both types of group. The daily attendance rate for Group A was 91.8% (range 58.2–100%), with four of the residents attending every meeting. For Group B it was 75.3% (range 52.9–94.1%). The difference in attendance between the two groups was significant (Mann Whitney $P < 0.048$) and may have been due to shortage of staff rather than residents' unwillingness to attend.

Staff ratings of residents' enjoyment was high for both groups (see Table III).

Overall effects of therapy programmes

Over the four-month period of the study CAPE Mental Ability scores declined for all three groups, but less for the two therapy groups than for the control group (see Table II). In spite of this decline, Group A residents improved on the other measure of cognitive ability (CAPE Information/Orientation): By the end of the second stage, Group A residents had improved an average of 18.5%, compared with declines of 10.3% for Group B and 15.2% for Group C (see Figure 2). This improvement was largely maintained one month later, while Group C residents continued to decline, producing a significant difference at this stage between Group A and Group C (Mann Whitney, $P<0.048$).

On the Holden Communication Scale, which reflected the residential staff's estimates of residents' awareness, responsiveness and communication abilities, Group A residents had improved by an average of 25.9% after the two therapy stages, and by 27.4% at follow-up a month later (see Figure 3). In contrast, Group B residents had improved by only 11.7% at the final assessment, and Group C by 7.4%.

Group A residents also improved markedly on the behavioural measures compared with the other two groups. On the CAPE Behaviour Rating Scale they improved an average of 28.6% over the therapy periods and maintained a 27.0% improvement at follow-up (Fig. 4). In contrast, Group B and Group C scores showed little change. Similarly, on Jeffery's Problem Behaviour Scale (Fig. 5). Group A residents had improved an average of 34.9% by the end of therapy and maintained this at follow-up (36.1%; whereas Group B residents only improved by 13.9% and Group C by 5.5%, and even these slight gains largely disappeared at follow-up.

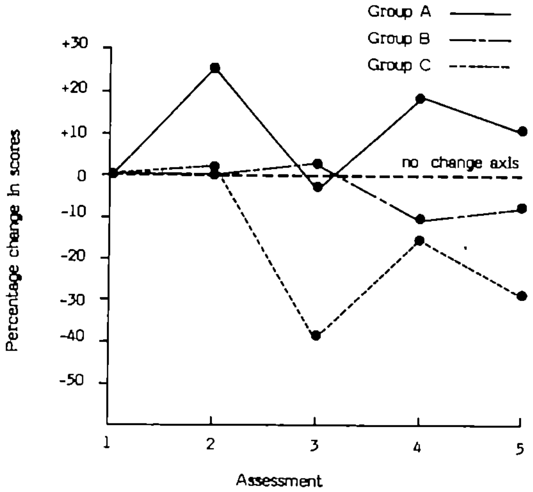

FIG. 2 Changes in mean CAPE "Information/orientation" scores for each of the experimental groups over the 4-month study period, showing percentage improvement (+) or decline (−) compared with the group's initial score.

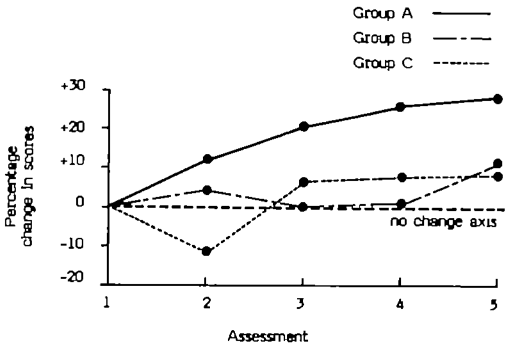

FIG. 3 Changes in mean Holden Communication Scale scores for each of the experimental groups over the 4-month study period, showing percentage improvement (+) or decline (−) compared with the group's initial score.

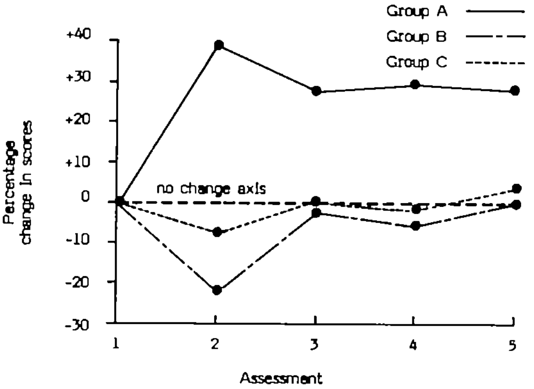

FIG. 4 Changes in mean CAPE Behavioural Rating Scale scores for each of the experimental groups over the 4-month study period, showing percentage improvement (+) or decline (−) compared with the group's initial score.

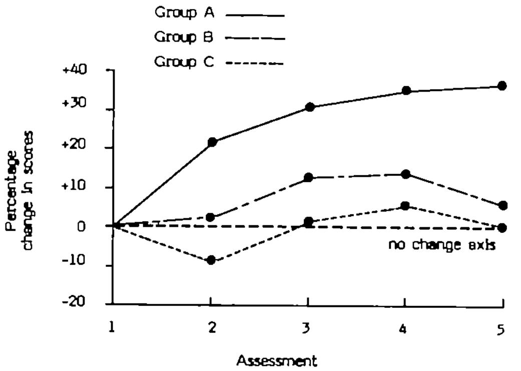

FIG. 5 Changes in mean Problem Behaviour Rating Scale scores for each of the experimental groups over the 4-month study period, showing percentage improvement (+) or decline (−) compared with the group's initial score.

Effects on staff

At the end of the therapy sessions the staff involved said that they knew and understood the residents in their own groups better than they had done before. The experimental evidence to support these statements is shown in Table IV. By the end of the study there was a very significant difference in the staff's knowledge about both therapy groups compared with the control group (Kruskal–Wallis $P < 0.009$, A *vs* B *vs* C; Mann Whitney $P<0.009$, C *vs* A; Mann Whitney $P<0.009$, C *vs* B).

All six staff said that they had enjoyed taking part in both types of groups and thought that the groups should be continued, and extended to other residents who were socially isolated but not necessarily confused; for example, to those who were avoided because they talked repetitively.

Once initial difficulties with a few non-involved staff and residents had been openly discussed, staff running the groups had encountered little resentment and much cooperation from their colleagues.

Discussion

The results of this study suggest that both reality orientation and reminiscence groups can be effective in helping staff to get to know moderately or severely confused residents. It also seems apparent from the high level of attendance, involvement and commitment that both kinds of group can be enjoyable and stimulating for both residents and staff. There was some evidence that the study had positive long-term effects on the residential staff; six months after the study ended, four of the six staff therapists (two from each therapy group) were running weekly sessions for three groups, using a combination of reality orientation and reminiscence techniques. The officers in charge, the staff who had run the groups (and some other staff) were enthusiastic about the effects of the research on the home: they said they were eager to receive more training of a similar nature and had already re-organised staff meetings so that they occurred regularly and were orientated towards staff training. Our results add some experimental support to previous suggestions that reality orientation (Powell-Proctor & Miller, 1982) and reminiscence groups (Norris & Abu el Eileh, 1982; Lesser *et al*, 1981) lead to both increased job satisfaction on the part of staff and improved quality of life for elderly institutional residents.

There was also evidence to suggest that some of the positive effects on group members were passed on to their non-participating room-mates, since room-mates improved on several measures during the therapy periods. This could be because of the increased communication skills of staff and group members. Our finding that these improvements in the control group were short-lived is in agreement with the findings of Brook *et al* (1975) that active involvement of therapists and clients is necessary for sustained improvement.

Group A residents showed greater overall improvement than Group B residents, which suggests that it may be important to use reality orientation techniques with confused residents *before* trying to involve them in reminiscence therapy. However, the results of our life-satisfaction questionnaire suggest that taking part in reality orientation sessions (as opposed to reminiscence therapy) can, for a short period, cause some individuals to report a lower level of life satisfaction. Even though the effect is not statistically significant, the trend is noteworthy since it was shown by Group A and Group B residents. It could be that initially reality orientation had a depressing effect on the mood of the residents because it forced them to face up to the reality of their situation. Indeed, before the sessions began some staff had expressed doubt about the wisdom of making mentally and physically impaired elderly people aware of the reality of their limited existence: they thought it might be kinder to allow them to continue to believe they were in a different time or place, even though that would mean that they were never able to adjust to the loss of their loved ones/or to the impairment of their own abilities; that they constantly asked for people who would never appear; that they remained isolated from the other residents, failed to recognise their visitors, and rarely participated in activities. However, our results suggest that this temporary but realistic lowering of mood may have been a necessary precondition for enjoyment of the present. Tape recordings from sessions and records of observations made by staff show that, as groups progressed and members got to know one another, members began to discuss openly both negative and positive feelings. They talked, mostly in groups but also after sessions, about themselves, about friends, their families, other residents, about their present situation and about their reasons for entering the home. This new-found ability to express emotions, including anger and sadness, appeared initially to alarm some members of staff and some non-group residents: before matters were resolved by discussion there were isolated attempts to discourage residents from attending group sessions. These discouragers reacted as if the groups were *causing* the anger and sadness, rather than confirming the reality of such factors as infirmity, bereavement and loneliness. The fact that the residents refused to be put off suggests that they felt a need to express these emotions.

The improvements in Information/Orientation achieved by Group A residents during their RO sessions (Stage I) were lost in the following month: this accords with the results of previous studies, (Miller, 1977; Greene *et al,* 1979; Feier & Leight, 1981; Powell-Proctor & Miller, 1982). However, in contrast with previous studies (Woods, 1979; Hanley *et al,* 1981; Zepelin *et al,* 1981; Powell-Proctor & Miller, 1982) these residents showed a significant improvement in behaviour compared with the other two groups, and this improvement was maintained in the follow-up period. Furthermore, the improvements in cognitive functioning of Group A residents during subsequent reminiscence therapy suggest that skills learned during RO may have continued to have a positive effect on their behaviour in this period. Although staff placed no emphasis on orientation-promoting material during reminiscence therapy, the residents talked spontaneously about topics such as recent events, planned outings, and current gossip about fellow residents at the beginning of each meeting. Similarly, the reminiscence therapy in Stage I for Group B residents seemed to affect their behaviour in Stage II, when they showed a preference for talking about their own past experiences and, initially, little interest in current events inside or outside the home. Many people enjoy reminiscence and, particularly if their present life situation is unfavourable, look back upon the past with nostalgia rather than as a rich storehouse of experience which could help them enjoy the present and look forward to the future. It is possible that reminiscence therapy reinforced the residents' and staff's inclination to avoid potentially upsetting topics, while the reminiscence component of reality orientation, with its emphasis on comparing both good and bad aspects of past and present, helped them to view both past and present experiences more realistically. Thus one might have anticipated our finding that residents who experienced RO first would do better than residents who took part in reminiscence first, and would have a better chance of deriving longer-term benefits.

The results indicate that a reasonably high level of functioning can be maintained for some time after formal sessions have ended and that losses in functioning which occur while residents are not in a group can be made up once groups restart; this suggests that groups need not necessarily run continuously to be effective. This could be important when considering the feasibility of running small groups in residential homes where staff have little time to devote to the social and psychological care of their residents (Evans *et al,* 1984). When we interviewed staff at the beginning of the study they expressed a desire to spend more time talking to the residents and getting to know them but said there was little opportunity to do so because they spent most of their working hours doing domestic activities and taking care of the physical needs of residents. Staff were also concerned that time spent talking to confused residents in small groups would be wasted, since the residents would not be able to contribute much and would not remember having taken part. However, our results suggest that the group experience prompted the staff to reappraise the ability of disabled residents to derive pleasure and other psychological benefits from small-group therapy. The staff also discovered that these kinds of sessions could be a useful means of increasing their knowledge and understanding of mentally disabled residents. Since staff continued to run groups and take part in in-service training long after the end of the study period it seems likely that their experience in the research project had caused them to reappraise their roles in caring for the elderly, and had increased their feeling that they were doing a worthwhile, rewarding job.

Acknowledgement

Our thanks for the interest and co-operation of the staff and residents of Outlands Residential Home, Plymouth.

Explorations of a Crisis Intervention Service

D. A. WINTER, H. SHIVAKUMAR, R. J. BROWN, M. ROITT, W. J. DRYSDALE and S. JONES

Descriptive studies of a crisis intervention service replicated previous findings of relationships between staff members' attitudes towards treatment and their 'personal styles'. The attitudes and personal styles of crisis team members and non-members differed, largely because of differences in the professions making up these groups. While all staff groups shared the same concept of crisis, they differed in their discrimination of crisis cases from 'furores'. Initial crisis intervention interviews exhibited more confrontation and less exploration by therapists than did initial psychiatric out-patient clinic interviews. Patients referred to the crisis team differed from significant other people in their lives, and from control patients referred to the ordinary out-patient clinic, in aspects of their perception of problems.

A 24-hour, family-orientated, psychiatric crisis intervention service was introduced at Napsbury Hospital in 1970, resulting in a significant reduction in psychiatric admission rates and in the number of new long-stay patients (Scott, 1980). It is now accepted as the model for psychiatric services in the London Borough of Barnet. The studies reported below focus on three aspects of this service: staff attitudes, therapeutic strategies, and the construing of clients referred to the crisis team.

Staff attitudes

The introduction of the Napsbury crisis intervention service was not without its problems, for "the old institution tried to terminate the existence of the team which initiated community practice" (Scott and Seccombe, 1976). Such resistance to change in the treatment policies of a clinical team or institution has also been noted elsewhere. Caine *et al* (1981) report how resistance to the introduction of a therapeutic community approach in a previously traditional psychiatric hospital ultimately led to the virtual abandonment of this 'adventure in psychiatry' (Martin, 1962). It also provided the impetus for a series of research studies which demonstrated that the attitudes to psychiatric treatment held by clinicians and by patients are a reflection of their more general attitudes to life and their 'personal styles'. More specifically, individuals favouring a medical/behavioural approach to treatment, in which an 'expert' therapist takes a predominantly directive role, were shown to be significantly more conservative and outer-directed than those whose preference was for a psychological approach in which the focus is more likely to be on interpersonal issues and where the therapist-patient relationship is less formal. Corresponding differences in attitudes and personal styles were found between staff working in different treatment settings, and the tension noted by Scott & Seccombe between staff involved in 'old' and 'new' approaches at Napsbury may also have reflected such differences. It was hypothesised, therefore, that members of the crisis team were more inner-directed and radical and had more 'psychological' attitudes to treatment than staff who were not involved in the crisis intervention service.

A further focus of the present study was the concept of 'crisis' held by crisis team members. Bloom (1963) demonstrated that American crisis theorists define a crisis as "an episode beginning with a known precipitating event followed by either no discernible reaction or by some reaction which required a month or somewhat longer to resolve". An elaboration of this concept, as used at Napsbury, was Farewell's (1976) introduction of the term 'furore' to describe the situation which occurs when behaviour, apparently precipitated by some current event, in fact reflects an unresolved crisis masquerading in a different form. It was predicted that crisis team members, unlike staff not involved in the intervention service, would differentiate between true crises (as defined by Bloom), furores, and non-crisis situations in terms of the management options which they considered appropriate for these.

Therapeutic strategies

Reviewing the literature on crisis intervention, Hobbs (1984) remarked that "there is little consensus among practitioners as to what constitutes crisis intervention. A variety of techniques is applied, in a variety of settings, to a wide variety of problems, by practitioners with a variety of skills and qualifications, and with a variety of aims". Similarly, Butcher & Koss (1978) pointed out that the "actual processes by which various crisis interventions bring about desired individual changes have not received enough attention to enable evaluation of them".

In view of such considerations, one of the aims of the present study was to unravel the components of the initial crisis interview, as practised at Napsbury. The concepts on which this interview was originally based were derived from crisis theory (Caplan, 1964) and from Scott's research on the families of schizophrenics (Scott & Ashworth, 1965, 1967; Scott & Alwyn, 1978). A central tenet of crisis theory is that there is a critical period in a person's response to crisis events during which he or she is extremely responsive to therapeutic intervention. For this reason, Scott & Seccombe (1976) saw the first crisis interview as being of supreme importance and as the beginning of treatment. They also considered that this interview should normally be conducted in the patient's family environment, as only there could the therapist prevent 'closure'–the severance of family bonds and avoidance of sensitive issues which contain the key to managing the crisis. In Scott's view, despite demands by the family for the patient to be pronounced mentally ill, the therapist should not succumb to the pressures of a lay diagnosis (Mechanic, 1962), but rather should keep in sight the basic human issues which have precipitated the crisis. His family research suggested that these issues concern a discordance between the perceptions of patients and parents–often between the patients' negative view of parents and the parents' view of themselves. Therefore, a major therapeutic task is "to get the patient to stand by his perceptions of the parents and not to abdicate them in favour of inner states" (Scott & Ashworth, 1967).

On the basis of these theoretical concepts, it was predicted in the present study that the initial crisis interview would be found to be characterised by therapeutic strategies in which the therapist took an active, confrontational role. In contrast, the initial psychiatric out-patient interview–the other major assessment option available to psychiatric patients living in the Borough of Barnet–was expected to be characterised by strategies in which the therapist's role was more passive and facilitatory.

Client constructions

In a pilot investigation of characteristics of patients referred to the crisis intervention service it was hypothesised that if a crisis is indeed a time of greater openness to change and flexibility, such patients would have less tightly organised personal construct systems (Kelly, 1955) than would patients referred to the out-patient clinic. It was also predicted that among the crisis referrals, the views which family members held of each other would be indicative of 'untenable' family relationships (Scott & Alwyn, 1978). Specifically, patients would be expected to perceive their family members more negatively than the family members perceived themselves. Conversely, crisis patients would construe themselves more favourably, and view their predicament less in terms of psychiatric symptomatology and illness than their family members construed them and than patients referred to the out-patient clinic construed themselves.

Scott & Alwyn (1978) used the Family Interpersonal Perception Test, asking family members to apply a set of attributions to themselves, other family members, and the others' view of them. There is now considerable evidence, however, that individuals find their own constructs more meaningful than supplied constructs when rating perceptions of themselves and others (Bonarius, 1977). Accordingly, the present study employed a repertory grid, using constructs elicited from the family members themselves, which it was assumed would be a more sensitive measure of clients' constructions than would the Family Interpersonal Perception Test.

Method

Staff attitudes

A battery of questionnaires was distributed to all clinical staff working in the two NHS psychiatric facilities serving the Borough of Barnet, and to all the general practitioners (GPs) in the Borough who agreed to be visited by a research assistant. The number of members of each professional group who completed the questionnaires, and the percentage of the total possible response from the group, are as follows: 12 psychiatrists (41%); 12 psychiatric social workers (63%); 3 clinical psychologists (75%); 11 occupational therapists (73%); 78 psychiatric nurses (12%); and 54 GPs (31%).

The questionnaire battery had five sections.

(a) Personal Information Sheet. This included questions on the subject's professional background and main and preferred areas of work. With the GPs, it was replaced by a structured interview focusing on attitudes towards the crisis intervention service.

(b) Attitudes to Treatment Questionnaire (ATQ) (Caine *et al*, 1982). High scores on this questionnaire indicate organic, and low scores psychological attitudes to psychiatric treatment.

(c) Direction of Interest Questionnaire (DIQ) (Caine *et al*, 1982). Introversion, in Jung's sense of inner direction of interest, is reflected in high, and extraversion in low scores on this questionnaire.

(d) Wilson-Patterson Attitude Inventory (Wilson, 1975). This measures conservatism (W1), defined as resistance to radical change, together with five of its components, referred to as 'realism' (W2), 'militarism-punitiveness' (W3), 'anti-hedonism' (W4), 'ethnocentrism-intolerance' (W5), and 'religion-puritanism' (W6). High scores indicate conservative attitudes.

(e) Case vignettes: These consisted of ten short case descriptions, four of which described cases which would be considered to be crises according to Bloom's (1963) definition, but which would not fall within Farewell's (1976) category of 'furore'. A further two vignettes described furores, while the situations outlined in the remaining four were neither crises nor furores. Subjects were asked to rate each case on four dimensions concerning their view of the problem; to rank alternative management options for the case in terms of their degree of appropriateness; and to place in preferred rank order different treatment possibilities (which were defined in an attached glossary). An example of each of the three types of case is provided in Appendix I as are the particular questions which were asked.

Therapist strategies

A series of 17 initial crisis interviews and 13 initial interviews at the psychiatric out-patient clinic were tape-recorded, and the tapes analysed in random order by a researcher who was blind as to the type of interview conducted. The system of analysis used was based on the method of Hawton *et al* (1982), which involves allocating every therapist statement (defined as all that a therapist says between two of the patient's statements) to one of nine possible strategies: Facilitation of communication; Exploration; Goal-setting; Informing; Interpretation; Approval/disapproval; Facilitation of emotions; Therapy rules; and Confrontation. The manual of definitions of these strategies was employed by the rater in deciding on appropriate strategy allocation, and where more than one strategy was used in one therapist statement, the predominant one was chosen. Modifications to the original procedure were that allocations to categories were made directly from recordings (i.e. typed transcripts were not used), and that entire interviews were analysed rather than excerpts. In addition to analysis of the whole interview, each interview was divided into four equal sections, and separate analyses carried out on each section. Raw scores for each strategy were expressed as percentages of the total number of interventions, to allow for differences in the length of interviews.

Client constructions

All contructs used by clients in describing themselves and other people were extracted from the tapes. Ten of the constructs elicited from the clients (identified patient and any significant others present at the interview) at each interview were selected (on the basis that they appeared dissimilar in meaning and relevant to aspects of the client's presenting problem) for use in a repertory grid which, if they agreed, was administered to the clients within a week of the initial interview. In the grid each client used the ten constructs elicited from his or her initial interview to rate (on a seven-point scale) the following people: the patient now; the patient before present problems; the patient as he or she will be after treatment; four significant others present at the initial interview (or the patient's mother, father, spouse, and one other significant person); the patient's GP; and two therapists present at the initial interview. Grids were administered to 17 of the patients referred to the crisis service and to 18 of their significant others. They were also completed by 13 patients referred to the psychiatric out-patient clinic, but it did not prove practicable to administer grids to the significant others of these patients. All grids were analysed by Slater's (1972) INGRID computer programme, and group comparisons were carried out on the variation accounted for by the first two principal components, and on measures of distance between various elements, between certain constructs, and between constructs and elements.

Results

Staff attitudes

Relationships between questionnaire scores

Significant inter-relationships were demonstrated between organic attitudes to treatment, outer direction of interest, and conservative social attitudes (correlations: ATQ with DIQ, -0.53, $P<0.001$; ATQ with W1, 0.50, $P<0.001$; DIQ with W1, -0.52, $P<0.001$; one-tailed tests). The only variables to show a significant relationship with age were conservatism and anti-hedonism.

Differences in questionnaire scores between staff members

Members of the crisis team had significantly more psychological attitudes to treatment and were more inner-directed than non-members, as well as obtaining lower scores on the 'militarism-punitiveness', 'anti-hedonism', 'ethnocentrism-intolerance', and 'religion-puritanism' scales (Table I). A further comparison of scores of staff members with a preference for working in the crisis team and those with no such preference revealed similar differences, in addition to the lower conservatism and higher realism of the former group.

In view of the differences in composition of the samples of crisis team members and other psychiatric staff, analyses of variance were carried out on the questionnaire scores, with crisis team membership and professional affiliation as independent variables. The results indicated that the differences between the crisis team members and non-members on all variables except conservatism, militarism-punitiveness and religion-puritanism were due to the differences in composition of these groups in terms of professional disciplines; the significant difference in conservatism between the groups was removed when age was included as a covariate in the analysis. Table II presents mean questionnaire scores of the different professional groups, together with the results of Scheffé tests on those variables with which the analyses of variance indicated significant differences

between these groups. On every measure social workers and nurses occupy the extreme positions, the former group being significantly more inner-directed and radical, and having more psychological attitudes to treatment, than the latter. Furthermore, these were the professional groups which differed most from the GPs, who were significantly more conservative, outer-directed, and organically orientated than the social workers, but significantly less conservative than the nurses.

Concept of crisis

Using Wilcoxon's test,[1] separate comparisons of median scores on response categories for the three types of case vignette were carried out on the responses of crisis team members, psychiatric staff not involved in the crisis team, and GPs. All staff groups were found to rate the crisis cases higher on the crisis dimension than the non-crisis cases, and to consider referral to the crisis team a more appropriate management option for them and crisis intervention a more appropriate treatment approach. Psychiatric staff, whether or not they were members of the crisis team, also regarded psychiatric admission as more appropriate for the crisis cases than for the non-crisis cases. However, only the crisis team members considered crisis intervention a more appropriate treatment option for the crisis cases than for the furores. The GPs considered referral to the crisis team a more appropriate form of management for the furores than for the crises; in common with psychiatric staff not involved in crisis intervention, they also regarded admission as more suitable for the furores than for the crises. Compared with the non-crisis cases, all staff groups rated the furores more highly on the crisis dimension, as well as considering psychiatric admission and referral to the crisis team more appropriate management options for such cases and crisis intervention a more appropriate treatment option.

Mann-Whitney U tests[1] indicated that crisis team members rated cases more highly in terms of their suitability for crisis intervention and for referral to the crisis team than did other psychiatric staff and GPs. In addition, crisis team members gave crisis cases higher ratings on the crisis dimension than did GPs.

Therapeutic strategies

Mean lengths of interview were 42 mins and 52 mins for crisis and out-patient interviews respectively; the difference was not statistically significant. The only significant differences between interview types in mean percentage scores on therapeutic strategies were the greater use of confrontation ($z = 1.85$; $P < 0.05$; one-tailed), and less frequent use of exploration ($z = 1.89$; $P < 0.05$; one-tailed) in the crisis interviews. Taken together, exploration and facilitation of communication accounted for the majority of therapist statements, while approval/disapproval was used least frequently in both types of interview.

However, as therapists conducting the two types of interview were not matched, the differences observed between interviews could have simply reflected differences in particular therapists' styles. In fact, it transpired that in each interview one of the therapists concerned made most of the interventions, and could be designated the 'primary therapist'. Only two of the primary therapists actually conducted both types of interview, while all other therapists conducted only one or the other. Data for these two therapists were therefore analysed separately;. and differences in exploration and confrontation between interviews were not only maintained thereby but actually increased ($z = 2.86$, $P < 0.001$ and $z = 2.01$, $P < 0.01$ respectively). Despite these differences in frequency of strategy usage between the two types of interview, there was little difference in their pattern of usage, exploration being employed less frequently and confrontation more frequently as interviews progressed, regardless of the type of interview (table available on request).

Client constructions

The construct systems of patients referred to the crisis intervention service were less tightly organised, in that the first principal components of their grids accounted for less of the variation than did those of patients referred to the out-patient clinic (Table III). Out-patients saw themselves as more highly characterised by their presenting complaints than did crisis patients, and imagined that they would change more, and become more similar to their ideal selves, following treatment. In the subsample of patients who used a construct of illness, out-patients also viewed their presenting complaints more in those terms than did crisis patients ($U = 2$; $P < 0.05$; one-tailed).

Table IV shows differences between the repertory grid scores of the crisis patients and the mean scores of their significant others. The significant others were more dissatisfied with the patients than the patients were with themselves, as well as seeing them as more highly characterised by their presenting complaints. They also showed a greater tendency to see the patient's present situation as representing a change from his or her previous state. The tendency for the patients to be more dissatisfied with their significant others than the latter were with themselves did not reach statistical significance.

Discussion

Staff attitudes

This study has provided cross-validation data for the Attitudes to Treatment and Direction of Interest Questionnaires, and has replicated the finding of Caine *et al* (1981, 1982) that clinicians' attitudes to psychiatric treatment reflect their more fundamental constructions of the world, i.e. their personal styles. Kelly (1955) has pointed out that any challenge to such core constructs is a threatening prospect, and so the introduction of the crisis intervention service at Napsbury may have posed a threat to those staff members who did not share the particular philos-

ophy which it represented. This possibility is highlighted by the predicted divergences in attitudes and personal styles observed between members and non-members of the crisis team, albeit largely because of their different composition in terms of professional affiliation. However, despite these divergences, some consensus of views was also apparent. For example, most of the GPs who were interviewed expressed general satisfaction with the crisis intervention service. Responses to the case vignettes also indicated that all staff members shared the concept of a crisis case which Bloom (1963) found to be held by American crisis theorists, although only crisis team members distinguished crisis cases from furores in terms of the greater appropriateness of crisis intervention for the former.

The questionnaire scores of crisis team members were similar to those of the therapeutic community staff studied by Caine *et al.* This may reflect the fact that both these approaches view psychiatric problems and their treatment in the context of social systems rather than in terms of 'mental illness', and it is of some interest that several of the staff who developed the crisis intervention service at Napsbury had been involved in a previous, unsuccessful attempt to introduce a therapeutic community. The scores obtained by different professional groups were also very similar to the normative data for such groups presented by Caine *et al.* Group differences of this order would suggest that interdisciplinary conflicts, ostensibly focusing on clinical issues, may in fact reflect divergences in more basic assumptions, values, and social and political attitudes. Although the customary low response rate from a postal survey casts doubts on the representativeness of these findings, it seems likely that the research will have been identified with the crisis intervention service in the hospitals studied, and that staff favourably inclined towards the service may therefore have been more likely to respond to the questionnaires. Such a sampling bias would lead to underestimates of the differences between the staff groups compared.

The present results point to the importance of attempting to change attitudes when introducing a new treatment approach, if it is not to meet with significant resistance. The induction of new members of a crisis team might also profitably focus on attitude change, particularly when a staff member is joining the team as part of a rotation scheme, rather than as a result of active preference for its style of work. Induction should also include explicit statements of the concepts and clinical strategies involved in crisis intervention, and of considerations which are relevant in deciding whether the approach is appropriate in a particular case (e.g. the distinction between crises and furores).

Therapeutic strategies

Evidence has been provided that the initial crisis intervention interview, as practised at Napsbury, is characterised by greater use of confrontation and less exploration by therapists than is the initial out-patient interview. However, the present investigation was essentially a descriptive study of current practice, and it was neither appropriate nor ethically desirable to match clients receiving crisis and out-patient interviews. The possibility remains, therefore, that the differences in therapeutic strategies observed between the two types of interview represent different reactions of the therapists to the two client groups concerned. Evaluation of the present results should also be tempered by the fact that no reliability check was carried out on the coding of strategies. This might have been particularly instructive in view of the fact that, although Hawton *et al* (1982) reported an acceptable level of inter-rater reliability for their coding system, reliability was poorest for codings of confrontation, which they found to be used infrequently in their crisis interviews.

Client constructions

Some, albeit slight, indication was provided that the construct systems of patients referred to the crisis service are less unidimensional than those of patients referred to the psychiatric out-patient clinic. As similar measures of looseness of construct organisation have been related to flexibility and to a greater likelihood of improvement in therapy (Fransella, 1972; Button, 1983; Winter, 1983), this finding lends support to the notion of crisis as a time of greater openness to change, and therefore susceptibility to therapeutic intervention. The tendency of the crisis patients not to construe their predicament so strongly in terms of defined presenting complaints or illness as did out-patients might also suggest a greater amenability to psychotherapeutically-orientated treatment. However, crisis patients also had less positive expectations of the outcome of treatment, or perhaps less motivation to change, and perceived less psychiatric disturbance in themselves than their significant others did in them. Therefore, in contrast to the untenable family relationships described by Scott (1973), the major discordance within the families of crisis patients appeared to concern the way in which the patient was perceived, rather than the way in which significant others were perceived. Nevertheless, the degree of this discordance suggests that family-orientated crisis intervention may have been a particularly appropriate approach to the problems presented by these families.

While these findings are in line with predictions, they require replication with a larger sample. The differentiation between referrals to the crisis team and to the out-patient clinic respectively may not have been an accurate reflection of the extent to which patients were in crisis, although therapists' ratings of the latter in the present study led to essentially similar results. In future research, a more precise indication of patients' degree of crisis might be obtained by the use of a life events measure.

A further shortcoming of the present study was that although the grid assessment was carried out within a week of the client's initial interview, when it was assumed that any crisis which had precipitated referral would still be operative, there was a possibility (and, indeed, this would be predicted in the case of crisis intervention) that the initial interview would already have had a significant effect on clients' construing.

The descriptive studies reported here will set the stage for prospective research comparing the treatment outcomes of, and examining changes in construing in, clients referred to the crisis team and those referred to a psychiatric facility which does not offer such a service.

Appendix

Examples of case vignettes

Crisis case. A female patient seeks help because her husband is carrying on an affair with another woman. The patient is tearful and says that for the past month, since becoming aware of the affair, she has felt miserable all the time, and has been unable to sleep or to decide on any course of action.

Non-crisis case. A youth of 17 asks for help because he has become increasingly aware of unwelcome thoughts about male friends, and is afraid he may be homosexual.

Furore. Since her marriage broke up, a middle-aged woman has been unable to manage her financial affairs, and whenever she gets into financial difficulties she presents with symptoms of anxiety. She is now presenting again, at the time of a rates increase, complaining that she is unable to sleep and asking desperately for help.

Questions asked concerning each case vignette

1. How do you see this problem? Please place a tick on each dimension
   (a) medical/physical ----- psychological/social
   (b) individual ----- family/marital
   (c) crisis ----- non-crisis
   (d) appropriate response to situation ----- inappropriate response
2. What would be the most appropriate way of managing the patient if he or she is presenting with this problem? Please assume that all the alternatives below are available and rank them in order of appropriateness from 1 to 8:
   (a) admit to psychiatric ward
   (b) place on waiting list for psychiatric out-patient appointment
   (c) refer to crisis team
   (d) refer to non-psychiatric specialist health care/social service, e.g. family planning clinic; marriage guidance clinic; social services (please specify if possible)
   (e) send to other community facility, e.g. Citizens' Advice Bureau; solicitor; Salvation Army hostel; police (please specify if possible)
   (f) should be dealt with by reassurance and advice from GP
   (g) should be dealt with by discussion of emotional difficulties by GP
   (h) does not require professional help.
3. What would be the most appropriate form of therapy? Please assume that all the alternatives below are available and rank them in order of appropriateness from 1 to 8. If you do not know what is involved in a particular treatment approach, please use the definition in the attached glossary.
   (a) psychotropic medication/other physical treatment
   (b) long-term insight-oriented psychotherapy
   (c) brief insight-oriented psychotherapy
   (d) supportive psychotherapy/counselling
   (e) family or marital therapy
   (f) behaviour therapy
   (g) crisis intervention
   (h) no treatment required
4. Comments and other alternatives.

Referrals to a Scottish Drug Dependence Unit
A Descriptive Study

M. M. O'ROURKE AND J. A. TAYLOR

The social and demographic characteristics, drug history and current levels of drug taking, drug-related illnesses, and criminal records of a one year cohort of attenders at the Southern General Hospital are described. The findings are compared with those of previous studies at the same clinic; made when methadone was prescribed for a limited period in reducing dosage and when this policy was being replaced by one of the use opiate-free drugs to cover withdrawal.

The misuse of drugs, and in particular of opiates, has increased substantially in the past 5 years. The number of addicts notified to the Home Office in Britain in 1983 (5850) was 42% up on the figure for 1982, and although the 1984 and 1985 figures are not yet available, social indicators of abuse (i.e. the seizure of drugs, the number of drug offences and attendance at clinics) suggest that the figures are likely to show an increase of at least that figure (Home Office, 1985). Ditton (unpublished) predicts a prevalence of 30 500 heroin addicts for Scotland by 1987.

Illegal drugs constitute a multinational industry worth many millions of pounds. The value of drugs seized in 1984 by HM Customs and Excise exceeded the 1983 figure by over 60%. These drugs, mainly cannabis, heroin, amphetamines, and cocaine, were worth £102 million at street prices. Estimates of successful detection rates vary between 5% and 10%; this suggests that illegally imported drugs worth £1000–2000 million found their way into Britain in 1984. It is worth noting that vast quantities of barbiturates and other drugs originate inside the country, and these in turn add to profits made on the illicit market (Institute for the Study of Drug Dependence, 1985).

Since 1980 Glasgow, in common with other European cities; has faced an increase in the availability of heroin on the illegal market. The attention it has received from the mass media has resulted in fear, confusion, and misinformation, emphasising the need for empirical research.

The Scottish Office has responded to the problems by funding several projects in Glasgow, Edinburgh and elsewhere in Scotland. The data in this paper are from referrals to one of these new projects – the Drug Stopping Programme (DSP) at the Southern General Hospital in Glasgow. The DSP available to drug takers is a modification of that described by Drummond *et al* (1986). Replacement opiates are not prescribed; withdrawal is aided by brief reducing prescriptions of chlordiazepoxide and temazepam. In-patient care is offered only to those whose physical or mental condition is sufficiently serious to warrant it. Access to the programme is open; appointments are available by telephone, and the waiting period between contact and appointment is rarely more than one day. First contact assessments are carried out by clinic staff on a rota basis. The process of assessment continues throughout the participant's contact with the programme, using a problem-oriented form of record. Data reported in this paper are taken from first contact interviews.

Method and results

Referrals

During the period of study (Oct. 1984 to Oct. 1985) 279 people were either referred to the programme or booked themselves in. Of these, 216 kept their appointments. The default rate of 22% compares favourably with that for new out-patient appointments in the Department of Psychiatry as a whole. Complete data were obtained from 172 of those attending; reasons for failure to complete the initial interview included time pressure, lack of co-operation, inappropriate referral, and intoxication. Forty percent of the 172 were self-referred; 27% were referred by general practitioners, 20% by social work agencies, 10% by casualty departments, 2% by employers, and 1% by the courts.

Drug preference

There appears to be a trend towards increasing variability in drug-taking behaviour. Although almost all of those interviewed expressed a preference for one drug or drug type over all others, it is clear that their drug-taking was by no means restricted solely to that. They were likely to have at least experimented with the full range of illicitly available mood altering drugs. In particular, the use of cannabis was universally reported by our sample.

Using the main 'problem' drug or drug of choice as the basis for classification, 84% (N = 145) took opiates, (the vast majority heroin); 6% took amphetamine sulphate; cannabis and LSD were causing problems with 3% each; and cocaine, barbiturates, benzodiazepines, and poly-drug abuse accounted for 1% each.

The more detailed description and comparisons below are restricted to the 145 opiate drug takers. The mean age was 22.6 (s.d. = 6.3 years); the modal age was 20, and 51% of the patients were under 21. Seventy-two percent were male.

Drug-taking variables

The mean age at which opiate drugs were first taken was 18.9 years (s.d. = 3.4 years), with a modal age of 17. Seventy percent of the sample had their first experience of opiates between the ages of 13 and 20. Twenty-one percent were taking opiates daily within one week of first exposure; 34% (figures are cumulative) within one month; 50% within three months; 68% within six months; and 93% within the first year. The mean duration of drug-taking prior to contacting the programme was 3.8 years (mode = 2 years). Only 8% of the sample sought help during the first six months, and 19% within the first year, of their addiction.

Estimation of the quantity of heroin consumed is complicated by variations in purity and in the way it is sold. Forensic evidence indicates that the purity of street heroin in the West of Scotland can vary between 8% and 20%. The price has remained reasonably constant over the past 3–4 years at £80/g. It may, however, be sold in 'score deals' of £25, £10 or £5 bags, all of indeterminate quantity; someone who buys eight £10 bags may well end up with less than the person who buys one gram. Differences in the form in which heroin is produced are likely to reflect the availablity of ready cash and access to different levels of the distribution network.

Given these considerations, the amount consumed is best presented in terms of cost rather than weight. At the time of interview 4% of the sample reported spending an average of £5/day or less on heroin; 25% spent £10/day; 25% spent £20/day; 29% spent £40/day; 3% spent £60/day; 10% spent £80/day; and 2% spent between £100–160/day.

Patients were also asked what was the maximum amount they had taken on any one day. Forty-four percent had taken £20–40 worth; 24% had taken £40–80 worth; 15% had taken £80 worth; and 17% had taken £80–160 worth.

The most common method of administration was injection, 73% of the sample using this route by the time of interview. Fourteen percent inhaled and 1% only smoked. Twelve percent took their drugs orally; these were predominantly cases where pharmaceutical products such as codeine linctus, dipipanone, or buprenorphine were the favoured opiates. Drug-related illnesses, predominantly hepatitis B or abscesses at injection sites, had been experienced by 37% of the sample. Four cases had suffered fungal infection of the eye. There were no reports of drug-induced psychosis or other acute reactions; 8% showed evidence of previous psychiatric disorder.

Almost half the sample, 46%, reported one period of abstinence from opiates; 38% reported two or more, and 16% had never been abstinent. There was little evidence that those who had previously attempted to give up drug-taking through their own efforts had been successful; most such attempts had lasted no more than two or three days. However, the mean duration of periods of abstinence for the sample as a whole was 93 days, because drug-taking had been prevented by imprisonment.

Social and demographic variables

Given the average age of the sample, it is not surprising that 74% were single. Sixteen percent were married or co-habiting, and 10% were divorced or separated. The overwhelming majority (93%) left school at the age of 16 without any form of qualification. Indeed, 32% claim to have effectively left school, through truancy, by the age of 15. Six percent had obtained 'O' levels, and one individual had achieved university entrance but failed to complete the course. Eighty-two percent were unemployed, and had been so for a mean duration of 2 years; 16% were working, and 2% were still at school or employed on youth training schemes.

Eighty-nine percent of the sample lived in local authority housing, 10% in privately rented accommodation, and 1% were of no fixed abode. Sixty percent lived with their parents.

There is little evidence of a social support network available to the sample. Only 29% said that they had friends who were not opiate drug-takers; the remainder stated that all their circle of acquaintance had drug-taking habits similar to their own.

There is a clear association between drug-taking and criminal behaviour: 84% of the sample reported financing their drug-taking through crime, predominantly shoplifting and other forms of theft. There were no reports of crime involving violence against a person. Charges were pending against 65%, and 66% had previous convictions, not all related to drug-taking.

Comparison with other samples

In comparing this sample with those from the same unit in 1983 (Fraser & Leighton, 1984) and 1984 (Drummond *et al*, 1986), a number of interesting points come to light (Table I). The best comparison can be made with Fraser & Leighton's sample, since both their study and ours looked at characteristics of attenders (Drummond *et al* mainly investigated the replacement of the prescribing service by the opiate-free day programme currently in operation). The sample of Fraser & Leighton were prescribed methadone for a limited period, in reducing dosage. Fraser & Leighton studied all patients attending the unit at the time, and the dates of first contact thus spread over a number of years; they analysed the data for those whose first contact occurred after 1981 separately, however, and found no significant differences.

Both the mean age at first contact and the age range have decreased since Fraser & Leighton's study (Table I)

TABLE I

Comparisons between three cohorts of referrals to a drug dependency unit

	Fraser & Leighton (1984) (n=80)	*Drummond et al (1986) (n=63)*	*Present study (n=145)*

1. Period before contact with any drug agency
2. Period before contact with the clinic where study was carried out

(although the drop is not statistically significant). The initial conclusion might be that drug-taking is becoming popular among younger individuals, due to the greater availability. However, this view may be simplistic. Drummond *et al* (1986) argue that the changes in service provision marked by the introduction of the DSP has made the unit more attractive and available to the younger drug-taker. This trend appears to have continued.

The marital status of both samples also differ. There are more single people in the present sample; this may be because the age group as a whole is younger, or it may have resulted from more chaotic living associated with illegal drug-taking. The number of unemployed persons in the sample is roughly similar, as is reported psychiatric history.

The proportions of patients in the two studies having had criminal convictions was similar. However, in contrast, a greater proportion of the present sample (84%, compared with 30% of Fraser & Leighton's sample) admitted to being engaged in illegal activity to finance their drug taking. A possible explanation for this difference may be that the individuals in the earlier sample found it difficult to admit to criminal activity, as medication was dependent on some measure of conformity.

The mean age for first use of drugs was similar across all three samples. There was an interesting difference in the percentage of patients who were never abstinent: this figure was 44% in Fraser & Leighton's sample, but only 16% in the present sample. Forty-six percent of the present sample were abstinent more than once, while in Fraser & Leighton's sample the figure was only 17%. This improvement may be attributable to health education advertisements encouraging people to attempt to stop using hard drugs. It may also be related to the expense of the habit; when people are paying for the drugs themselves, as in our sample, they are more likely to need to control how much they use.

Discussion

This paper describes the clientele of one of Glasgow's drug clinics; it may or may not be typical of others. The generalisations that can be made from this sample are limited by the fact that only a minority (5–10%) of drug-takers attend a drug dependence clinic (Ditton, 1981). The comparison of this sample with that of Fraser & Leighton (1984) shows these opiate takers to be remarkably similar demographically, although younger. It is possible that younger drug takers are coming to the clinic because staff at the unit are now full time specialist addiction counsellors, with an open appointment system.

The majority of the sample lived with their parents or with a partner. Most have no qualifications, and are unemployed. The level of crime reported is high, and even this may be an underestimate. Roughly one-third of patients gave a past history of hepatitis, which is comparable with figures found in other studies (Stimson & Ogbourne, 1970; Woodside, 1973; Fraser & Leighton, 1984; Drummond *et al*, 1986).

Although we have studied referrals to the DSP, rather than causal factors of drug addiction, some comments regarding the latter are worth making. Speculations about causes of heroin addiction include unemployment, peer pressure, and availability of drugs. In the present sample, 82% were unemployed at the time of first contact. Unfortunately, we do not have data regarding their employment status at or before the time of first use of drugs and unemployment is high in this sample's area anyway. Closer investigation is needed before any relationship can be determined.

Seventy-one percent of the sample reported that all of their friends used heroin. Again, this figure relates to the time of first contact and not to their situation at or before the time of first use. However, 84% reported that they first used drugs in the peer context (either at parties, in pubs or in the company of friends). Again, the peer pressure or social learning theory requires further empirical examination.

Finally, most patients reported that heroin was easily available to them. Perhaps this availability made it more likely that individuals would try the drug in the first place.

These and other factors associated with causation (such as personality factors or rebellion against authority) merit further detailed and long-term investigation.

Comparison of Electrical Measurements on Constant Voltage and Constant Current ECT Machines

R. RAILTON, J. FISHER, A. SINCLAIR and J. M. SHRIGMANKAR

Electrical measurements were made during treatment of two groups of patients, one group receiving treatment from a constant current ECT machine and the other from a constant voltage machine. The electrical impedance and energy were calculated and compared for the two groups. More energy was delivered by the constant voltage than by the constant current machine, but the spread of energy delivered was comparable. With a consistent technique for applying the electrodes there is little to choose between these machines, but the constant current machine may be preferred where consistency cannot be achieved.

The DHSS report on electro-convulsive therapy (ECT) recommends the introduction of constant current instruments for delivering the electrical energy required (Department of Health and Social Security, 1982). This recommendation is based on the fact that the more commonly used constant voltage device delivers a varying amount of current, depending on the electrical impedance between the electrodes (e.g. a person with half the average impedance would receive twice the average current). The electrical energy delivered by the constant current device would however still vary depending on the impedance encountered.

Two groups of patients chosen for ECT treatment were studied, one group receiving treatment from a conventional constant voltage machine and the other from a constant current apparatus. Electrical measurements were made during the treatment, and comparisons made of various electrical parameters. Assessments were also made to monitor the effectiveness of the treatment using routine clinical criteria, but a clinical trial of the two machines was not undertaken.

Method

Clinical

Twenty-two recently admitted in-patients suffering from acute depression were selected for ECT treatment on clinical grounds. The absence of organic lesions was confirmed where necessary by routine investigations (including skull X-rays and brain scans); nine patients received skull X-rays, and five subsequently had a brain scan. The results of these tests were negative. None of the patients were on any medication, and none had had cranial surgery or skull trauma; none of them had received a course of ECT in the previous three months.

The patients were randomly divided into two groups, without the knowledge of the referring clinician. Group A (2 males, 8 females, mean age = 53) received therapy with a constant voltage apparatus (Ectron Duopulse Mark 4) and Group B (1 male, 11 females; mean age = 45 years) with a constant current apparatus (Ectron Series 2A). The constant voltage device produces a biphasic truncated sine wave with an amplitude of approximately 170 V at a frequency of 50 Hz. The duration of the administration was 1.7 s (85 pulses). The constant current device produces a square wave with amplitude 850 mA, 1.25 ms pulse width, and a repetition frequency of 40 Hz (manufacturers' data). The duration of the administration was 4 s (160 pulses). A course of treatment typically consisted of six ECT administrations, but some had as few as three and one as many as ten.

For both groups bilateral ECT was administered under general anaesthesia (thiopentone) with a muscle relaxant (suscamethonium chloride). Two-handed electrodes were used, soaked in Ectronolyte (sodium bicarbonate and sodium sesquicarbonate) solution (one sachet dissolved in 285 ml of water). Treatment was given using the standard method of applying the electrodes across the temples. At the time of administration the presence or absence of bilateral convulsion was noted; when present, the duration of the convulsion, from the onset of the electrical energy to the last clonic twitch of the great toe, was measured. The administration was carried out by a registrar; over the period of study six individuals were involved.

Patients were reassessed clinically at three months by the referring clinician, who was not present during the administration. Treatment was considered to be successful if the patient could be discharged from the clinic.

Technical

The current and voltage pulses produced by the ECT machine were displayed on an oscilloscope at the time of administration to the patient (Weaver *et al*, 1974). The measuring circuit (Fig. 1) presented a load of 105 kΩ to

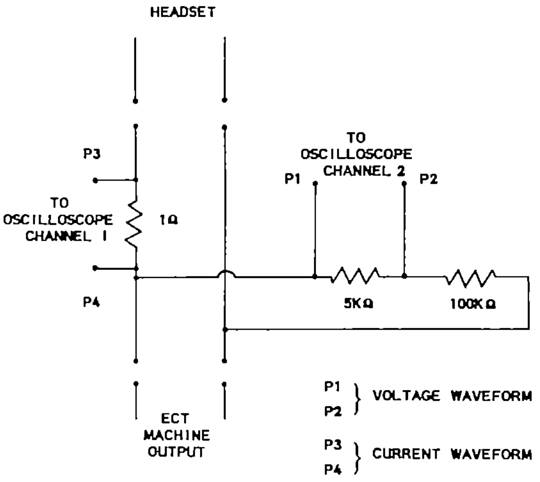

FIG. 1 Electrical circuit used for measuring the voltage and current waveforms.

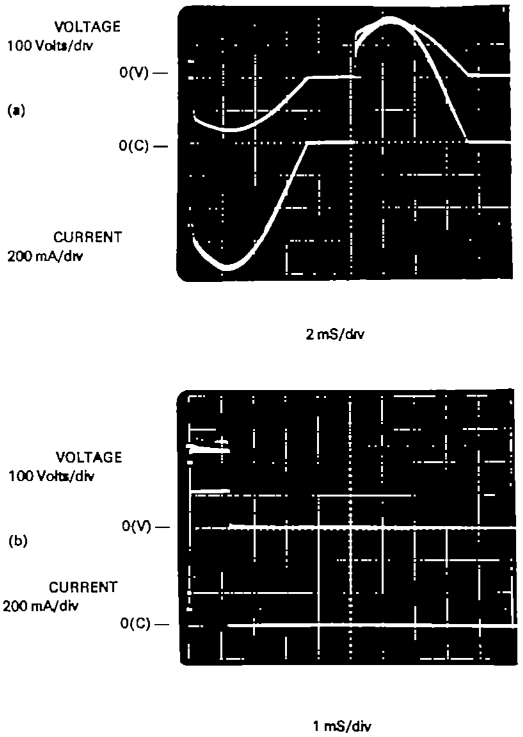

FIG. 2 (a) Cumulative recording (open-shutter photograph) in one subject of oscilloscope tracings (approximately 85) of voltage and current waveforms produced by the constant voltage ECT machine; (b) cumulative recording (open-shutter photograph) in one subject of oscilloscope tracings (approximately 160) of voltage and current waveforms produced by the constant ECT machine.

the ECT machine; this had an insignificant effect on the delivered power (for an inter-electrode resistance of 250Ω the effect is to reduce the resistance to 249.4Ω, which produces a 0.24% difference in the delivered power). A Polaroid camera was used in the open-shutter mode to photograph these pulses, and the resulting photograph (Fig. 2) represents the sum of the pulses produced during each administration. From these photographs the peak voltage (V_p) and peak current (I_p) were determined, and hence the impedance (V_p/I_p) between the electrodes could be calculated, along with the energy delivered. For the constant voltage waveform the energy was calculated using the formula $E = 0.25\ V_pI_p \times 1.7$, derived using the assumption that the sine wave was truncated at the peak value. For the constant current waveform the energy was calculated with the formula $E = 0.05\ V_pI_p \times 4$, derived using the assumption that rectangular pulses of duration 1.25 ms were occurring every 25 ms. The mean values and standard deviations for a series of measurements in each patient were calculated and used to find the mean and standard deviation of the group.

Results

Clinical

In Group A, out of 50 ECT administrations only two failed to produce a convulsion. Similarly, in Group B there were only two failures in 77 administrations. The mean duration of the convulsions in Group A was 32 s (s.d. = 8 s), and in Group B it was 32 s (s.d. = 4 s). The treatment as assessed at three months was judged to be clinically successful in seven out of ten patients in Group A and in eight out of twelve patients in Group B.

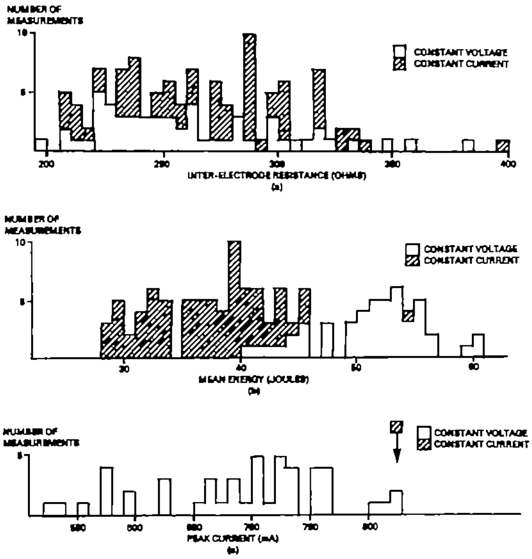

FIG. 3 Distribution of resistance, energy and current values for 50 constant voltage and 77 constant current administrations: (a) resistance; (b) energy; (c) current.

Technical

The photographs of the electrical pulses show that the electrical impedence presented to each machine was purely resistive, since there are no phase differences between the current and voltage pulses. These waveforms confirmed the general characteristics of each machine claimed by the manufacturer, and there was no evidence of additional short duration pulses (transients). The distributions of the resistance, energy, and current are shown in Fig. 3. The mean energy delivered to Group A was 51 J (s.d. =4 J), the mean resistance was 254Ω (s.d. = 31Ω), and the mean current was 700 mA (s.d. = 50 mA). For Group B the mean energy delivered was 37 J (s.d. = 3 J), and the mean resistance was 274Ω (s.d. = 22Ω); these values are significantly different from those for Group A ($P < 0.001$ and $P < 0.05$ respectively; Mann-Whitney U test).

Discussion

The clinical response to ECT in our study was comparable with that reported by other workers (Medical Research Council, 1965; Weschler *et al*, 1965), although no attempt was made to match their research criteria.

The wide variation in inter-electrode resistance reported by Gordon (1982) was not seen in our study. In the ten patients who received constant voltage therapy the minimum resistance was 200Ω and the largest resistance 320Ω, and in the case of twelve patients receiving constant current therapy the minimum resistance was 235Ω and the maximum resistance 380Ω. The slight difference (8%) observed between the mean values was probably due to systematic errors in the measurements of the voltage and current. The main source of the electrical resistance is the contact resistance between the electrodes and the skin of the scalp. Wide variations in resistance can be accounted for by variations in the application technique. Since the standard deviations in the measurement of resistance in individuals (mean across Group A = 29Ω, s.d. = 18Ω; mean across Group B = 34Ω, s.d. = 14Ω) is comparable with the standard deviation of the whole group 31Ω for group A, 22Ω for group B, it would appear that the variability is due to technique and not to variations in physiology. The small spread of the measurements found in our trial reflects the consistency of application of the electrodes by six different individuals. In addition, the concentration of the solution used to soak the electrodes was the same for each application.

The mean energy delivered by the constant voltage device is 38% higher than the mean energy delivered by the constant current device, but the range of energies delivered is comparable in the two cases. These results show that with consistent application of the electrodes, the advantages of the constant current device over the constant voltage device are not realised, in terms of variation of energy delivered. However, although most of the energy delivered by either device is dissipated in the electrodes, proportionately more energy is delivered to the brain by the constant voltage machine than by the constant current machine. Since this trial does not suggest any added advantage in this situation, it is probably desirable to reduce the energy delivered by the constant voltage machine by reducing either the voltage or the duration of the pulses.

The value of energy measurements in determining the convulsion threshold has been questioned (Gordon, 1982), with peak current measurements being favoured instead. Patients receiving treatment from the constant voltage machine experienced peak currents ranging from 520–830 mA (mean = 700 mA), compared with the constant current treatment which was all nominally at 825 mA. The two occasions when no convulsion was observed with the constant voltage machine involved patients on whom peak currents of 550 mA and 762 mA were

TABLE I
The effect of changes in inter-electrode resistance

Inter-electrode resistance: Ω	*Constant voltage*[1] *machine*		*Constant current*[2] *machine*	
	Peak current: mA	*Energy:* J	*Peak current:* mA	*Energy:* J
200	838	57	850	29
300	606	46	837	43
390	488	39	825	54
510	388	33	688	50
1000	220	20	388	31

1. Biphasic, 50 Hz, 1.7 s duration.
2. 40 Hz, 4 s duration.

measured. Two failures to produce a convulsion also occurred with the constant current machine; the only common feature of the four episodes was an indication that a slightly higher dose of muscle relaxant was administered, and this may have masked the presence of the convulsion. However, even if these applications are not excluded it would appear that an adequate peak current was present to stimulate a convulsion in 96% of constant voltage and 97% of constant current administrations.

The effect of changes in inter-electrode resistance (obtained by placing resistors of known value between the electrodes) can be seen in Table I. With the constant voltage machine, increasing resistance causes less energy to be delivered, whereas with the constant current machine more energy is delivered until the constant current characteristic cannot be maintained (above 450Ω). Consequently the latter machine is less dependent on variations in electrode application, since it will compensate for variations in the contact resistance of the electrodes.

In conclusion, with consistent techniques of electrode application there appears to be little advantage in either the constant voltage or constant current ECT machine, but it may be desirable to reduce the energy delivered by the constant voltage machine. Where consistency cannot be achieved, the constant current machine offers some advantages.

Acknowledgements

The constant current machine used in this study was purchased by a grant from the Lanarkshire Health Board Research Fund. The authors wish to thank Sister H. Thomson and the staff of the Psychiatric Unit at Monklands DGH for their co-operation during this study.

Brief Reports

Varieties of Combat Stress Reaction
An Immunological Metaphor

The use of an immunological metaphor allows the incorporation of established theoretical ideas about trauma and stress in an integrative way which enables delineation and illustration of several varieties of combat stress reaction, including subtle forms of that condition which do not often appear in post-traumatic stress disorder literature.

Traumatic experience and the Israeli population are inseparable. The Holocaust, immigration, the eruption of five wars, as well as continuous military tension, all condensed into a short span of history, have unfortunately had a wide traumatic impact. The abundance of accumulated clinical data, as well as work with Holocaust survivors and psychological war casualties, has shown us that the post-traumatic experience has many expressions and takes many forms.

The concept of combat stress reaction (CSR), a sub-category of post-traumatic stress disorder (PTSD) (American Psychiatric Association, 1980), has suffered from the lack of a unifying explanatory model. Clinicians have tended to one of two theoretical concepts. The first uses Freud's (1921) idea of trauma, in this context to describe a massive emotional shock of such power that it breaks past the defence mechanism and floods the person with uncontrollable anxiety. This implies a highly specific individual vulnerability based on previous early experience, which persists in its power to immobilise afresh. The second and more recently elaborated major theoretical model is that based on the model of stress and coping (Cannon, 1929; Selye, 1956), which describes the accommodation of the organism to general stress. This biological stress model has been expanded to include psychological and social factors, such as occur in the battle situation (Lazarus, 1966; Titchner & Ross, 1974).

These two explanatory theories, while not contradictory, are not conceptually unified. Our ongoing experience with war casualties has revealed variations and nuances in the clinical expressions of CSR that required an approach using both models in combination. The immunological metaphor we have chosen, while not an explanatory model, runs like a thread between the two theories, exploiting the inherent nature of the immune defensive response: current adaptive responsivity based on previous exposure. Thus, the immune metaphor includes both explanatory models, without invalidating either, and facilitates further exploration of PTSD.

Characteristics of the immune system

The immune system is a defence system. It is reponsible for maintaining physical health, and in turn requires for its proper functioning overall integrity of other systems of the organism. To understand the immune metaphor, some of its unique operational modes (Kimball, 1983) must be made clear.

(a) The immune system has both general, innate defensive properties, independent of contact with a foreign substance (antigen), as well as acquired, specific protective responses that are gained through contact with foreign substances (antigen-dependent).
(b) It identifies and reacts to outside noxious elements.
(c) When confronted by an overwhelming, massive exposure to inimical elements, it may fail.
(d) It has a unique ability to memorise identifying features of the threatening element. Once sensitised, it may mobilise an enhanced response when rechallenged by even small amounts of the original threat. Thus, smaller and smaller challenges may produce larger and larger responses.
(e) The immune response may be either immediate or delayed.
(f) Once activated by a specific foreign substance, the response may later be cross-activated by less specific substances, thus changing from a highly specific response to a generalised reactivity.
(g) The immune response can be protective, but it may also miscarry and become self-destructive, creating a new form of illness.

Varieties of acute combat stress reaction

Immediate CSR

Immediate CSR occurs when a psychological system is overwhelmed by a massive, life-threatening situation. The defence capability, if present at all, is initially fragmentary, dissociated, and uncoordinated, and the response undifferentiated and amorphous. This is analogous to an overwhelming assault by a virulent infection, to which the body cannot mobilise an adequate immune response in time. This common battlefield entity is illustrated by the following case-history.

A 25 year-old tank crewman, after three days and nights of continuous action during which many of his comrades were killed, lost communication with his unit. He was discovered in a mute, disorientated state, wandering aimlessly in the desert, and was so overwhelmed with anxiety that he had to be evacuated by helicopter to a field hospital.

Acute CSR

The clinical picture of acute CSR is that defined by DSM–III under the category of acute PTSD. It involves such symptoms as: re-experiencing the traumatic event; numbing of responsiveness to, or reduced involvement with, the external world; and a variety of autonomic, dysphoric, or cognitive symptoms. Just as the clinical symptoms of an infection reflect the product of the invading and the defending forces, so the acute combat reaction may be seen as reflecting a duel between the anxiety-provoking, painful, and as yet unintegrated memories and emotions on the one hand, and the defensive efforts to block, seal off, or dampen them on the other. This rise in defensiveness may be reflected both in increased intrapsychic defensiveness and in behavioural-interpersonal responses such as irritability, decreased sociability, and withdrawal. It is this dynamic interplay of the anxiety and the attempt to overcome it which is so characteristic of acute CSR, and which determines the form of the ultimate outcome, whether towards resolution or towards chronicity.

The soldier described in the previous section became coherent after two days, and was then transferred to a rear-echelon psychiatric facility. His disorientation continued to improve, but he was troubled by nightmares, and by flashbacks of battle scenes during his waking hours. He was extremely irritable, hypersensitive to noise, and subject to bouts of crying, while at the same time reluctant to discuss his battle experiences. His complaints gradually abated, and by the end of five months he was sufficiently symptom-free to resume normal activities.

Missed immediate CSR

As in the immune system, the resistance to combat stress depends on the degree of previous preparedness (innoculation), and on the intactness of the surrounding support systems. As in most infections, the natural history of immediate CSR tends in most cases towards spontaneous remission. A certain proportion of these cases would therfore not be recognised or documented (Moses & Cohen, 1984), and as such could be defined as missed immediate CSRs. Whether the immediate condition remits, or persists to evolve into acute PTSD, the subject, like the immune system, becomes sensitised. He is thus permanently altered, harbouring the potential for a future enhanced response on re-exposure to a similar threatening stimulus; this lays the foundation for a possible delayed reaction.

Varieties of delayed combat stress reaction

On exposure to trauma, regardless of whether or not there is an acute response of the kinds mentioned above, there is always the possibility of a delayed response (Archibald & Tuddenham, 1965). This is analogous to delayed responses in the immune system; the use of the immune metaphor assists in discerning the delayed forms of PTSD.

Reactivation of combat reaction

Just as an exposure to a minimal amount of allergen in a sensitised patient may lead to an extreme reaction – even tranaphylactic collapse – so may soldiers who have suffered previously from frank, acute CSR collapse under minimal military exposure, years later.

A 25 year-old infantryman, diagnosed as suffering from acute CSR in the Yom Kippur War of 1973, returned to full functioning in civilian life, including family and work involvement. He managed to maintain his equilibrium until call-up, 11 years later, to the war of 1982. From the moment he received his mobilisation papers he became increasingly anxious, and finally collapsed on arrival at his unit, as it was preparing for the field.

Reactivation of missed combat reaction

This is a variation on the reactivation of CSR, mentioned above. Just as a patient who appears to develop a massive hypersensitivity reaction for the first time is found to have suffered subclinical, undiagnosed previous responses, so a soldier suffering from an unexpectedly severe combat reaction may be discovered to have undergone an antecedant, unnoticed CSR.

A 28 year-old soldier was evacuated with a full-blown CSR, which at first sight seemed to have been generated by a relatively minor battle stimulus: the chance sight of a casualty, witnessed from afar. In treatment it became clear that this disproportionate reaction actually originated from a trauma sustained in a previous war, when he suffered a severe CSR, which went undiagnosed at the time but which nonetheless, served to sensitise him.

Displaced combat stress reaction

Hypersensitivity, once established, may generalise and turn into cross-sensitivity, which implies development of the full-blown immune response, provoked by a wider range of less specific stimuli (Christenson *et al*, 1981). Similarly, a CSR may be provoked by a life event completely unrelated to war, occuring in a civilian setting.

A 31 year-old civil engineer developed a full-blown PTSD, following the death of his father. His symptoms consisted of guilt-laden dreams and flashbacks related to the tramatic war experience of six years previously, from which he had not suffered in the interim.

Our experience indicates that almost any life event which bears some relationship to any facet of the original trauma has the power to create a displaced CSR: e.g. loss of any kind, such as the death of a family member, divorce, road accidents, or dismissal from work.

Delayed combat stress reaction

The clinical picture of delayed CSR is, like the acute type, defined by DSM–III under the heading of PTSD, chronic or delayed. The symptoms are essentially the same as in acute CSR, except for the time element. The symptoms either endure for six months or more, or develop at least six months after the trauma (Archibald & Tuddenham, 1965).

The delayed CSR can be likened to an illness developing months or years after the exposure to the invading agent. The form of the illness is the product of the late expression of the bodily immune defences, which have become over-responsive and harmful in their own right. An example is tuberculosis, where the patient may present suddenly with a serious cavitating lung condition due to hypersensitivity to the bacillus, many years after first becoming infected

A 24 year-old soldier experienced many frightening combat situations, which evoked fear, anger, and grief at the loss of comrades. He continued his military function, although feeling "robot-like'. At the end of the war he was discharged normally and returned to civilian life, continuing university studies and renewing social contacts. Increasingly, he felt that he "wasn't the man he had been previously". He was surprised that he had mounting difficulty in concentration, unexplained depressive feeling, and was unable to enjoy life. Suddenly, without an apparent trigger, seven months after discharge, he developed sleeplessness and nightmares about friends who had died in the war; he also had flashback phenomena, and became apathetic and immobilised.

Retrospective combat stress reaction

In certain immunological illnesses, such as serum-sickness, a circulating foreign substance will develop enhanced antigenic properties, when the host later develops sufficient antibodies to cause a reaction. Similarly, there are soldiers who develop a changed attitude to previous war-related experience, so that re-evaluation of combat memories produces a stress reaction which was originally absent. This altered perception may be as a result of changed circumstances in their lives, particularly changes related to attachment and bonding, such as marriage or the birth of a child. These changes, which would be seen by life-cycle theorists such as Erikson or Maslow as healthy psychological growth and maturation, cause a more disturbing light to be shed on what was previously perceived simply as an adventurous event or a necessary unpleasant duty. The subject develops the capacity to imagine and to identify with the emotional consequences of killing and being killed, so that fragments of previous experience become retrospectively traumatic. This phenomenon has been noted in the Holocaust literature (Krystal, 1968), as in the case of the woman who, as a young girl, witnessed with relative emotional detachment the bashing to death of a baby plucked from its mother's arms by SS guards. Only after attaining motherhood herself, many years later, was the woman able by identification to experience the full horror of such an event; she then became severely anxious at the prospect of losing her own baby. New attachments may thus produce alteration in basic attitudes, so that veteran, married soldiers may now find it impossible to perform military functions that were once easy for them, and are statistically more at risk to develop CSR than their younger, single, comrades-in-arms (Solomon *et al*, 1984).

A 25 year-old soldier who experienced many frightening events as a member of an elite special-forces unit subsequently married and had a child. These new attachments in his life altered his perception of his previous close encounters with extreme danger, and he reported some anxiety at the thought of what he had been through in the past. He stated that the battle experience, previously perceived as adventures, had acquired a new frightening dimension, reported vague tension at the idea of being called up again, and was embarassed to discover that he was immobilised with anxiety. On rejoining his unit, he was suffering from a condition identical to immediate CSR, was unable to continue serving there, and was referred for psychiatric care.

Discussion

The clinical picture of CSR, and hence of PTSD, is richer than appears in the current literature. DSM–III has enabled broad categorisation of the nuclear syndrome of PTSD, while providing a valuable diagnostic tool (Solomon *et al*, 1984) for the identification of CSR. Our accumulated clinical experience through several wars reveals that the varieties of CSR are numerous and subtle, so that the immune system has proved to be a particularly useful metaphor in delineating and presenting them in a systematic way. This metaphor highlights the complexity of the interplay between stumulus and response, as well as the multiform clinical nature of combinations in which they appear. It reduces the relevance of the dispute over the importance of the source of the trauma – whether early or late, intrapsychic or interpersonal, personality-related or stimulus-related – and so contributes towards simplifying the paradigm that has troubled clinicians working in the field of trauma. Although essentially biomedical, it serves to incorporate psychosocial-aetiological factors in an integrative way. Moreover, the metaphor has important and direct ramifications, both in its preventive and therapeutic implications; while we have found it useful in discerning the varieties of CSR, we believe it is no less useful for civilian work, e.g. in the general hospital setting (Kutz *et al*, 1986).

Heroin Abusers in Psychiatric Beds

A Glasgow Study

A retrospective study was carried out of all heroin abusers admitted to an acute psychiatric unit to examine their use of the facility of in-patient care. The compliance with treatment was low. Most patients discharged themselves or were discharged prematurely for using drugs while in the ward; only 21% were discharged as planned. The value of hospital admission in the management of opiate abusers may have to be reconsidered in view of the increasing prevalence of heroin abuse and the limited number of psychiatric beds.

The admission of opiate abusers to hospital for in-patient detoxification was once considered to be a mainstay in their management (Home Office, 1968), but is not now thought to be so important (Thorley & Plant, 1982). It may be a useful first step in a longer programme of rehabilitation involving either community projects or therapeutic communities (Department of Health and Social Security, 1984). In the London drug dependence clinics detoxification is usually carried out on a long-term out-patient basis (Ghodse, 1983). In Glasgow the recent rapid rise in heroin abuse (Ditton & Speirits, 1982) and the reluctance of psychiatrists to prescribe opiates on an out-patient basis has resulted in admission to acute psychiatric units continuing to be used as the main psychiatric response to the problem in many hospitals.

In theory, the benefits to be gained by admitting a heroin taker to hospital are

(a) assessment of physical health and of social and personality factors influencing the drug abuse
(b) management of the physical and psychological withdrawal symptoms in a supportive and controlled environment
(c) provision of 'time out' from the drug scene
(d) opportunity to plan changes in lifestyle
(e) introduction to a community-based project for continued rehabilitation.

The psychiatric service of Glasgow Eastern District, based at Duke Street Hospital, regularly admits heroin abusers to acute psychiatric beds. Initial screening is done on an out-patient basis by a senior psychiatrist to confirm the diagnosis, identify the level of abuse, and assess motivation. In-patient care is offered if appropriate, and patients are usually admitted within three weeks. The duration of in-patient care is flexible, being dependent on the patient's progress as assessed by staff.

Following admission, assessment of physical health is carried out and appropriate treatment given. If there is objective evidence of opiate withdrawal symptoms (such as pupillary dilatation, tachycardia or sweating), medication in the form of oral methadone, chlordiazepoxide or clonidine is prescribed. Random urine screening is undertaken frequently during the patient's stay to detect any surreptitious use of opiates in the ward. Patients are informed beforehand that their use of drugs in the ward will generally result in their discharge. During the day patients attend sessions of group psychotherapy and occupational therapy.

This study was carried out to examine the use of this facility of in-patient care by a group of opiate abusers and their progress.

Method

All heroin abusers who were admitted to the ward between 1 June 1983 and 31 May 1985 were included in the study. Their case records were examined to obtain basic epidemiological data, drug history and details of their progress in the ward.

Results

Over the two year period 56 heroin takers were admitted (41 men and 15 women). In most cases (84%) referral was made by general practitioners, but referrals were also made by other medical specialties (14%) and by social workers (2%). The mean age of the patients was 22.7 years (s.d. = 4.24 years, range = 14–36). Although most were single (79%), none lived alone.

Drug use

The mean reported duration of opiate abuse was 3.4 years (s.d. = 2.16 years) and all patients had been regularly injecting opiates intravenously before admission except for four who had been taking the drugs by insufflation. It was difficult to obtain precise information on the daily amount of opiates taken, as this was usually expressed as the amount of money spent on heroin per day. The mean reported amount spent was £37/day (s.d. = £25.5/day, range = £5–120/day); at the time of the study the patients reported the price of 'street' heroin to be £80–100/g, although its purity and potency varied widely.

Progress in the ward

Only 20% of the patients did not require medication to relieve withdrawal symptoms. Most patients (61%) received oral methadone given in reducing doses from 30 mg/day over eight days. A further 14% received chlordiazepoxide (initially 80 mg/day), and 5% were given clonidine (initially 0.2 mg/day), both these drugs being given orally.

Most patients (61%) either discharged themselves or left the ward without permission and did not return. A further 18% were discharged by medical staff after urine tests confirmed that they had been using opiates surreptitiously in the ward. Only 21% remained in the ward until their planned date of discharge. A total of 31 patients (55%) achieved a drug-free existence while in the ward in that they were neither receiving prescribed drugs nor using drugs surreptitiously, but many of these patients discharged themselves shortly after reaching this stage.

Those who remained in the ward until their planned date of discharge had (as expected) a longer mean duration of stay (32.7 days; s.d. = 17.2 days) than those who took their own discharge (10.2 days; s.d. = 10.5 days). Seven patients (12%) took their own discharge after only one day. Those who were discharged prematurely for using opiates while in the ward had a mean length of stay of 28.3 days (s.d. = 23.4 days).

Premature discharge was not associated with the non-prescription of medication; indeed, those who completed their stay were slightly less likely to have received medication (25% received no medication), and 90% of those who were discharged due to using drugs surreptitiously had initially been prescribed methadone.

Discussion

At this hospital one heroin abuser is admitted on average every two weeks; these patients are typical (in terms of age and sex) of heroin abusers attending other drug dependence clinics in Glasgow (Fraser & Leighton, 1984). More than half reach a drug-free state, however short-lived, while in the ward, but many of these patients discharge themselves shortly afterwards. Most patients do not remain in the ward until their planned date of discharge but discharge themselves after an average of ten days. A further number are discharged by medical staff for using opiate drugs surreptitiously while in the ward.

The prescription of medication to ameliorate withdrawal symptoms seems in anything to have a negative effect on satisfactory progress, although it is possible that the patients who required such medication were more severely dependent or less motivated and therefore less likely to remain in the ward. If is difficult, however, to quantify withdrawal symptoms, and the value of admission may lie in the 'time out' element rather than in pharmacological detoxification. In addition, the relatively long period of time after admission (28 days) before many patients started using opiates in the ward suggests that the longer-term craving for the drug, perhaps enhanced by boredom, is just as likely to produce relapse into using drugs again as the acute withdrawal symptoms. For this reason, much emphasis is placed on using the period of in-patient care to introduce the patient to a longer-term programme of rehabilitation in the community to prevent future relapse. Since most patients discharge themselves before this can be properly effected, much doubt is thus cast on the overall usefulness of admission.

The main shortcoming of the study is the lack of objective long-term follow-up information on the patients. We have had little success in arranging for these patients to attend the hospital for follow-up, which is perhaps a result of the policy here of not prescribing substitute drugs on an out-patient basis.

The significance of the frequent outcome of irregular self-discharge is also uncertain. It is possible that those who discharged themselves irregularly from the ward were just as likely to lead a drug-free existence thereafter as those who remained until their planned date of discharge. However, the often sudden, impulsive and desperate nature of the wish to leave hospital in these cases suggests that it probably indicates imminent relapse. Even if admission to hospital does not result in total abstinence thereafter from opiate use, though, it may have a significantly beneficial effect, perhaps by reducing the degree of dependence or by decelerating a process of physical and social deterioration.

The practice of admitting heroin abusers to psychiatric beds may not be a completely useless exercise, and currently accounts for a small proportion of psychiatric bed occupancy, but the poor compliance observed in this study suggests that this form of management now needs to be examined more critically in the current climate of limited psychiatric resources and an ever-increasing population of heroin abusers seeking psychiatric help.

Capgras Syndrome: A Case Report from Zimbabwe

A case of Capgras syndrome in a black Zimbabwean patient is described. The syndrome occurs in the setting of a schizophrenic illness, but psychodynamic factors are readily identified despite the patient's different cultural background.

Early clinical descriptions by French authors (Magnan, 1893; Janet, 1903; Capgras & Reboul-Lachaux, 1923) referred to 'l'illusion des sosies' (the illusion of doubles), and it was not until 1929 that the term 'Capgras syndrome' was suggested (Levi-Valensi, 1929) in recognition of that author's contribution. For some years the syndrome was believed to be rare (Enoch & Trethowan, 1979), but recent reports indicate that it is much more common than was formerly suspected (Quinn, 1981). Berson (1983) reviewed the English literature, and found 133 cases. A report has also been received from Jamaica (Sims & White, 1973), and in Africa Collomb (1965) described the characteristic misidentification in one of his patients but did not identify the syndrome. We were unable to trace any other report of its occurrence in a black African patient.

Case report

A 27 year-old single, unemployed black male patient was admitted to Harare Hospital in June 1982 with a three-day history of violent and aggressive behaviour towards his father, and also of consuming large quantities of alcohol and stripping in public. On admission he told the staff angrily that his father was not his father but only a "caretaker", who was forcing him to visit various *ngangas* (traditional healers) with the intention of proving that the father was in fact the real father. He further alleged that the surburb of Mufakose, where the "caretaker" resided, was not real either but a carbon copy of the genuine town.

The patient's belief that the real father had been substituted by a "caretaker" began five years before admission, when the patient suddenly resigned from his job because "the boss was looking at him in a queer way". The following day, his father took him to discuss this with a priest. While the discussion was in progress the patient waited outside. He then observed that an impostor and not his father emerged from the church. He was certain that it was an impostor because of the differences which he noted: the real father was a kind, caring, religious and good person, whereas the "caretaker" was a fat, ugly, mean and strict person, who wanted to make the patient a slave in the house. The "caretaker" somehow knew the patient's thoughts and prevented him from taking a job. The patient further believed that the "caretaker" was bewitching him.

The father reported that from that time the patient had never again addressed him as "father" but invariably referred to him as "that man". The patient became argumentative, disrespectful and often broke household objects. Once he threw away the family radio because it was broadcasting news about him. He suspected that neighbours were plotting against him and that his family had poisoned his food. He often spoke to imaginary people.

Except for the delusional content, there was no evidence of thought disorder at the time of admission. Auditory hallucinations were present: the patient could hear the voices of his ancestral spirits comforting and commending him, and sometimes discussing him in the third person. The patient's account of himself was given with a moderate pressure of speech and with much circumstantial detail. His affect was angry and hostile. There was no evidence of either depression or elation. Consciousness was clear, and cognitive function normal. Physical and neurological examinations revealed no abnormality; investigations for syphilis, malaria, trypanosomiasis and cannabis intoxication proved negative. The electroencephologram was within normal limits.

While on the ward, the patient claimed that he could distinguish the "caretaker" from his father by his greater obesity, different voice, and facial expression. After one visit by his parents he insisted that the "caretaker" had a different watch and had hair like a European (i.e. straight, not tightly curled). His mother tried to convince him of his father's authenticity, but he retorted that the "caretaker" was trying to seduce her into marriage; he accused her of having divorced her real husband. Occasionally he wondered if his mother were an impostor as well, but this idea never assumed delusional strength.

Personal background

The patient was the eldest of 8 siblings. At the age of two he was sent to live with his grandparents in a rural area. During early childhood he lived a carefree life tending cattle, fishing in ponds and playing in mud pools. After the sudden death of his grandfather he returned to his parents at the age of eight years. His father was a hard-working factory worker in Harare, a religious man who was strict with his children. On his return home the patient had to start school, attend church daily and refrain from playing with dirty children in the neighbourhood. As the eldest of the family he was subjected to extra pressure and discipline to succeed academically. At the weekends he had to spend most of this time in social service connected with the church. His mother was a quiet, unassuming, dependent woman who never challenged her husband's opinions or instructions about bringing up the children.

In this atmosphere, the patient grew up to become a quiet, shy, lonely, obedient and studious adolescent. He could neither develop any peer group activities nor mix readily with girls; he had profound feelings of guilt over masturbation. After two unsuccessful attempts to pass his 'O' level examinations he left school at the age of 20 to become a painter's assistant. His father wanted him to study further, and repeatedly admonished him for failure. He continued to have difficulty mixing with people, and developed no relationships with women; he became a heavy drinker. After a year at his job he left because he was convinced that his colleagues were somehow against him.

Course and outcome

A diagnosis of paranoid schizophrenia was made, and treatment began with chlorprimazine (1000 mg/day). The symptoms gradually subsided over the next four weeks, and after six weeks in hospital the patient was discharged to the care of his parents. He was followed up as an out-patient for the next 18 months. He stopped addressing his father as "caretaker" or "that man" and once again called him father. He took a job at the same factory where his father worked, and expressed a feeling of shame that he had treated his father with disrespect during his illness.

Discussion

As our case illustrates, Capgras syndrome occurs in schizophrenia, but many authors have stressed the importance of organic factors (Weston & Whitlock, 1971; MacCallum, 1973; Hay *et al*, 1974; Hayman & Abrahams, 1977; Preskon & Reveley, 1978; Waghray, 1978; Shraberg & Weitzel, 1979; Alexander *et al*, 1979; Madakarisa & Hall, 1981) and some have seen it as an adaptational manoeuvre in old age (Goldfarb & Weiner, 1977).

It seems remarkable that such a specific syndrome should result from diverse pathological processes. The double is always a significant person in the life of the patient (who does not misidentify others), and is usually accused of not possessing the features the patient would like the original to possess. Such features strongly suggest the operation of psychodynamic factors, and it also seemed remarkable to us that such factors could be readily identified in our patient despite his non-European cultural background.

In Shona culture, feelings of love and respect towards one's father are accepted as normal; hostile feelings are expected to be suppressed from conscious expression.

A father is responsible for the moral upbringing of his son, and any disrespect shown towards one's father is regarded by society as a moral crime against the ancestral spirits. In our patient, these traditional values of filial respect were inculated by his grandparents (it is common to send a child who has been weaned – usually at about two years of age – to keep the grandparents company). These values were subsequently reinforced by a rigidly moral and religious upbringing. There is evidence that the father attempted to drive the boy academically which, together with peer group rejection, is a common cause of disturbance during adolescence (Buchan, 1971). It seems likely that our patient developed hostility towards his father and dealt with it by repression.

This intrapsychic stress, his difficulties in interpersonal relationships and his recourse to alcohol may have been precipitating factors for his psychotic illness.

Intense suspiciousness has often been observed prior to the onset of the Capgras delusion (Capgras & Reboul-Lachaux, 1923; Enoch & Trethowan, 1979) and our patient exhibited this kind of projective defence when he left work. With the development of the psychotic process and the failure of the early defences, the defence of splitting emerged. The patient's internal representation of his father was split into good and bad individuals (Arieti & Bemporard, 1974), and the bad individual was seen as an impostor. The message from our patient seemed to be quite clearly "Father must change". The motive appeared to be adaptational – an attempt to reconstruct the environment by replacing the current non-giving, unacceptable father by a warm, nurturant one.

Despite his regligious commitment, the patient's father had taken him to many *ngangas* in the hope of finding a cure. This accounted for the long delay between the onset of the illness and his being brought for treatment. The hospital was seen as a last resort when the patient became violent, which is probably the case with the majority of patients in this setting.

Ganser Syndrome

A Case Report and Discussion

A case of Ganser syndrome occurring in an 11 year-old Indian boy is described, and the psychodynamics and nosological status of the syndrome discussed. Ganser syndrome should be regarded as a hysterical state, and should not be confused with the similar picture observed in organic brain syndromes and psychoses.

In 1897, Sigbert Ganser delivered a lecture on 'A peculiar hysterical state'. Later, after having examined twenty such patients, he refined his description of the clinical syndrome which now bears his name (MacDonald, 1977). It is also often called 'prison psychosis', 'syndrome of approximate answers' or 'hysterical pseudodementia' (Sim, 1974). The most important feature of this syndrome is that the patient gives incorrect and often ridiculous answers, despite having comprehended the question (this is termed '*vorbeireden*'). Whitlock (1967) regarded the condition as a psychotic one, occurring either after acute cerebral trauma or in the course of an acute psychotic illness. Many other authors agree with Ganser's original diagnosis of a special kind of hysterical dissociative state. The cases described by Ganser were all prisoners, but the syndrome is not confined to criminals (MacDonald, 1977). The condition is rare, especially in children.

Case report

An 11 year-old boy was referred for psychiatric evaluation with a five-day history of attacks of hysterical unconsciousness and periods of confusion during which he gave wrong answers and claimed amnesia for certain events. Fifteen days before admission he had experienced several fainting attacks; these had been attributed to evil spirits. At the onset of his presenting symptoms he suddenly started weeping loudly and complaining that he was not being given proper attention.

The patient lived in a village with his paternal grandparents, while his parents and two younger sisters lived in Bombay. The only educated member of the family was the father, who completed high school. The patient's mother tongue is Marathi, but he was sent to an English-speaking school as his grandparents had high expectations of him. He was initially regarded as a bright student, but his scholastic performance had deteriorated over the two years before admission.

The majority of the villagers were farmers and labourers, and placed little importance on education. Because the village had only a primary school which taught in Marathi, the patient attended a school in the neighbouring city. Since he was the only such student from the village, he was singled out from the village boys, and had no close friends among them. There was no-one who could help and guide him in his studies.

An English education is considered essential in India for upwards social mobility. The patient was thus under tremendous pressure to achieve good school results, despite the linguistic, scholastic and social difficulties that he had to face.

Throughout his childhood he demanded and received prompt attention from all his family. He had many food fads, and would have temper tantrums at the slightest provocation. He would always try to dominate his sisters and mother.

The immediate precipitating factor for his illness was his grandparents' refusal to send him on a school excursion. His fainting attacks followed the refusal, and his major symptoms started when his friends returned from the excursion.

The results of his physical and neurological examination were normal. On mental status examination he demonstrated *vorbeireden*. While counting to one hundred he omitted a few numbers; and answered that ten plus two equalled eleven. He initially claimed amnesia for his school's and village's names, but remembered them after a few minutes. He suddenly and dramatically developed hiccups, which stopped spontaneously when no attention was paid to them, and displayed *la belle indifference*.

After admission he showed a dramatic recovery, which was consolidated by giving suggestion during sodium pentothal interview. During psychotherapeutic interviews he stated ambitions to become a lawyer, a physician or an engineer. He drew a house, and said that in it lived two girls with their parents. Despite the obvious reference to his sisters and parents, he could not elaborate further. He accepted that he was finding it difficult to do his study in English. On intelligence testing his IQ was 107.

Discussion

This is the first case report of Ganser syndrome in an Indian child. Kanner (1972) reported a case of Ganser syndrome in a six year-old girl; he was able to find only one other report of the syndrome occurring in children.

Ganser specified four major features of this syndrome (Arieti & Bemporad, 1974): giving approximate answers, a clouding of consciousness, somatic or conversion symptoms, and hallucinations. Of these, the first symptom is essential. Our patient had the first three symptoms. Although headache is the commonest somatic symptom reported, in this case conversion symptoms (hiccups) and dissociative state (unconsciousness) were prominent features. The patient's personality development clearly showed hysterical traits, such as immaturity and demanding and manipulative behaviour. The syndrome has never been reported in a person of high intelligence; this patient, although regarded as bright by his parents, was of average intelligence.

Lehmann (1976) stated that in almost every case the patient finds himself in a confining situation. Such a situation was not found in this case. Although the patient was under stress, particularly as a result of approaching examinations, he did not view himself as trapped or confined.

Arieti & Bemporad (1974) suggested a simple psychodynamic mechanism for the syndrome: the patient wants to avoid an unpleasant situation and the burden of responsibility. This was the situation in this case: the patient was finding his schooling increasingly frustrating, his end-of-year examination was approaching, and he could not accept the possibility of failure. An illness with dramatic cognitive difficulties provided him with an excuse for subsequent poor performance. This is the secondary gain in this case. The presence of conversion symptoms, dissociative state, secondary gain, and response to suggestion favours the view that Ganser syndrome is a hysterical state and not a psychotic illness.

Whitlock (1967), in his review of the literature, concluded that the condition is a psychotic one. However, he himself accepted that the cases described in his paper and the majority of the cases described by other authors did not have even the majority of the symptoms described by Ganser in his original paper. It is advisable to accept Scott's (1965) suggestion that a differentiation should be made between Ganser syndrome and Ganser symptoms (approximate answers). Ganser symptoms are comparatively common, and are usually seen in acute functional or organic psychoses, while Ganser syndrome is clearly hysterical in nature.

Folie à Deux in Down's Syndrome

A Case Report

A case of folie à deux in a 29 year-old man with Down's syndrome, whose mother had a paranoid psychosis, is described. Successful treatment of the mother's illness also resulted in full recovery of the son without the need for medication.

In their classic paper of folie à deux, Lasègue & Falret (1877) stressed that the first condition for its development in an individual is that "he be of low intelligence and "better disposed to passive docility than to independence". Tuke (1887) also suggested that induced psychosis is more likely in the "feeble-minded", and Gralnick (1942*a*) described folie à deux in two sisters, one of whom was mentally subnormal.

Various psychiatric abnormalities may be observed in Down's syndrome (Parsons *et al*, 1984), but there have been no reports of folie à deux in combination with this disorder. We report such a case here.

Case report

Mrs A., a 77 year-old woman, was first seen at her home at the request of her general practitioner. She complained that two young women who had escaped from prison were living in the rafters of her house; they had moved in six months previously, shortly after her husband was permanently admitted to hospital with a stroke. She claimed that they were particularly noisy at night, when they banged on her bedroom ceiling and window, threw insults at her and her 29 year-old son who lived with her, and clambered up and down drainpipe outside singing hymns and chanting "incy wincy spider, climbing up the spout" as they went. She believed the women to be in league with the next door neighbours, whom she thought broke into her kitchen at night to steal food and money, but were clever enough to leave no trace.

Mental state examination revealed a thin small suspicious woman who looked her age. She showed no depression of mood, disorientation or memory impairment, and displayed no insight into her delusional beliefs.

Her son had the physical features of Down's syndrome, and later chromosomal analysis confirmed trisomy 21. When interviewed separately he confirmed his mother's story and said that he sometimes heard the womens' voices independently from her; for example, they swore at him whenever he flushed the toilet at night, told him that his father was dead, and threatened to cut his throat if they caught him.

Mrs A. had married at the age of 27, and in addition to her son had three daughters, all of whom were married and lived away. She and her son were very close and mutually supportive, but he also enjoyed his daily attendance at a local training centre. He was socially competent, being continent and ambulant and having good self-help skills. He had no previous history of psychiatric illness or behavioural disturbance. Mrs A. also had no past personal or family history of mental illness, but was described by her family as having always been eccentric and domineering. Her psychosis appeared to start at about the time of her husband's hospitalisation, and in association with unexpected family bereavements and conflict with her neighbours over an aggressive dog. Following these events she became increasingly withdrawn and frightened, stopped her son from attending his training centre, and slept in the same bed as him for protection.

A diagnosis of paranoid psychosis was made in the mother and of folie à deux in her son. She was treated at home with trifluoperazine and community psychiatric nurse support, but refused to take her medication or agree to be physically investigated; however, she responded well to fluphenazine decanoate injections. Her son remained at home with his mother during this period, and his delusions and auditory hallucinations resolved completely without the need for treatment as her mental state improved. On later psychological testing he was found to be cheerful, sociable and co-operative, and was able to give the date and month but not the year of his birth. He was unable to read, but could name the letters of the alphabet, showed good colour and shape matching, and was able to cope with quantities up to four, however, he was unable to deal with more than two combined qualities or to seriate. At the age of 5 his IQ had been 52; his current IQ was assessed at 45. Speech therapy assessment using the Reynell Language Development Scales revealed that his comprehension was at the level of a 5 year-old, but that his expressive ability was that of a 7 year-old.

The results of subsequent physical examination and laboratory, radiological and neurophysiological investigations on Mrs A. were normal except for a low serum vitamin B_{12} level of 80 ng/l (normal range 180–960 ng/l); a Schilling test revealed an intrinsic factor defect, and she was started and maintained on intramuscular hydroxocobalamin. There has been no return of her psychosis despite the discontinuation of fluphenazine decanoate, and her son, who now lives in a group home and continues to attend his training centre, remains well.

Discussion

People with Down's syndrome are reputed to have a special talent for mime (Down, 1866), and imitation may be an aetiological factor in folie à deux (Gralnick, 1942*b*). However, we do not consider that the psychotic features observed in the son can be explained entirely on the basis of mimicry. His delusional thinking was well systematised, and even extended to unique symptomatology. Moreover, this case fulfils the diagnostic criteria of folie à deux suggested by Dewhurst & Todd (1956): positive evidence of intimate association; a high degree of similarity in the general motif and delusional content of the partner's psychosis; and the partners accept, support and share each other's delusional ideas. The case also has several other classical features: withdrawal from normal social interaction, dominance of the partner with the primary psychosis, and the sharing of the same bed. The reputed suggestibility associated with Down's syndrome may also be significant in our case, as highly suggestible individuals are said to acquire delusions more easily in folie à deux but also to shed them more readily (Dewhurst & Todd, 1956).

Acknowledgements

Thanks are due to Mr T. Foxen for administering the psychological tests and to Mrs K. Wallis for the speech therapy assessment.

Psychiatric Presentation of Creutzfeldt-Jakob Disease

A Case Report

A patient with Creutzfeldt-Jakob disease is described. Many alternative psychiatric diagnoses were considered, and the true situation only became apparent late in the clinical course.

The diagnosis of Creutzfeldt-Jakob disease is difficult, particularly in the early stages, because of the variability and complexity of its presentation. Often, therefore, no precise diagnosis or a wrong diagnosis is made during life (Matthews, 1983). Furthermore, the diagnosis remains essentially clinical, and the electroencephalogram (EEG) and computerised tomography (CT) scans, which are consistently abnormal in the later stages, are frequently normal for some considerable time after presentation (Kuritzky *et al*, 1980; Galvez & Cartier, 1984). Not surprisingly, psychiatric disturbances – which constitute the prodromal manifestations in 18–39% of cases (Will & Matthews, 1984; Brown *et al*, 1979) – are among the more difficult problems in differential diagnosis. The commonest early psychiatric symptoms of Creutzfeldt-Jakob disease include depression, emotional lability, asthenia, sleep disturbance and personality change (Will & Matthews, 1984). Such misleading pictures gain added importance in view of the precautions which ought to be observed over the handling of blood and other laboratory samples when the disease is suspected (Advisory Group on the Management of Patients with Spongiform Encephalopathy, 1981).

We describe in this report an unusual initial presentation which led to several psychiatric diagnoses being considered over the course of ten months before the features of Creutzfeldt-Jakob disease finally became apparent.

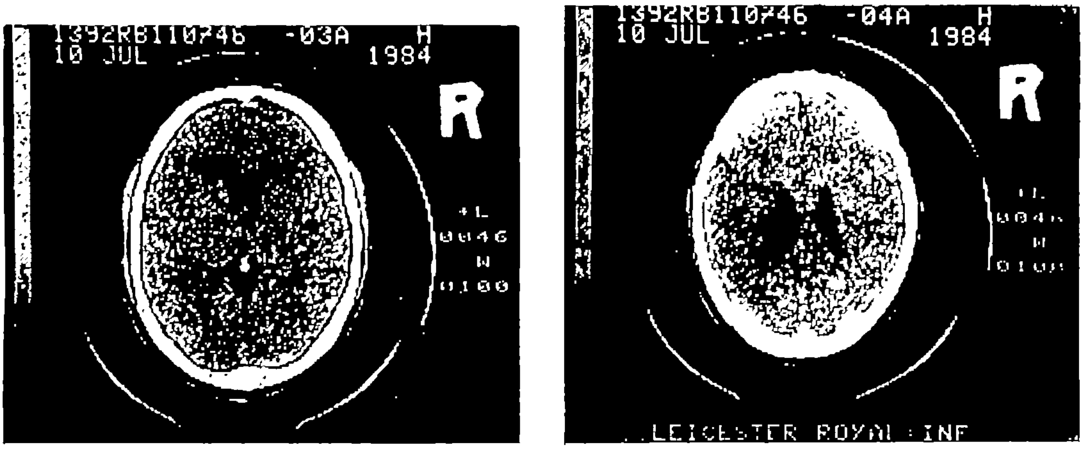
Case report

A 38 year-old antiques dealer was noted to be increasingly forgetful and disoriented from Christmas 1983. He had been a heavy drinker for many years, and particularly so in the preceeding 18 months, often consuming a bottle of spirits per day. He was also depressed because of growing tensions between himself and his second wife, centreing on his first wife's wish to send the two children of that marriage to live with him. There were episodes of his losing his way in his home town, and his business affairs had become increasingly chaotic.

When seen by a physician at the end of May 1984 he showed impaired memory and confabulation, but no focal neurological signs. A diagnosis of Korsakoff's psychosis was made, although depressive pseudodementia was considered a possibility. A brain isotope scan excluded the possibility of a cerebral tumour.

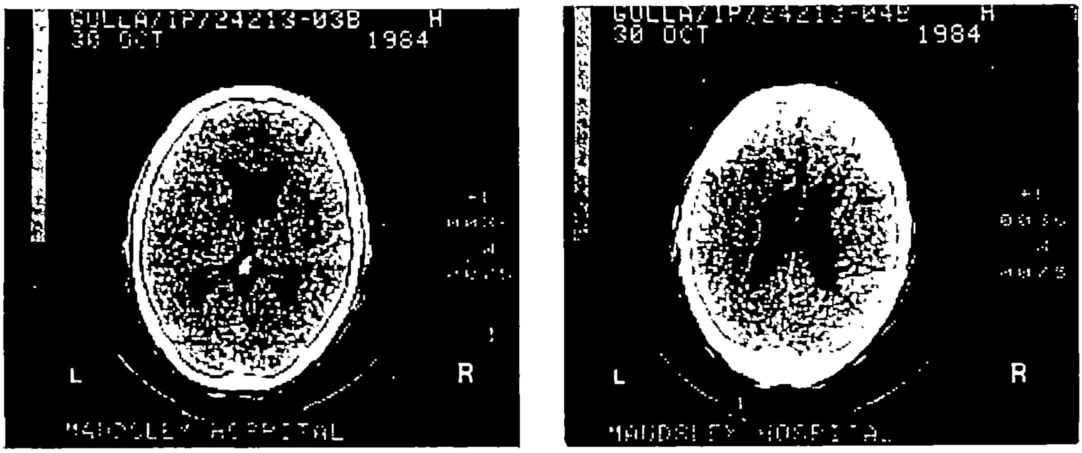
Despite discontinuation of drinking and a course of thiamine and antidepressants his symptoms worsened, necessitating admission to a psychiatric hospital in June 1984. On admission he was found to be disoriented and amnesic at times, but at others he was lucid and could give a good account of himself. No hallucinations or delusions were elicited. He was noted to be emotionally labile and gave approximate answers to questions, this leading to a diagnosis of hysterical pseudodementia or Ganser's syndrome. However, abreaction failed to clarify the picture further.

The following investigations were all normal: full blood count, syphilis serology, liver, thyroid and renal function tests, serum electrolytes, blood glucose, and serum B_{12} and folate. An EEG carried out on 7 August was difficult to interpret on account of restlessness and some involuntary



(a) (b)

FIG. 1 CT scan of patient taken in July 1984, 6 months after onset.



(a) (b)

FIG. 2 CT scan of patient taken in October 1984.

twitching of the limbs and head, but showed mixed theta and delta activity, the latter over the left temporoparietal region. These findings were attributed to a possible alcoholic encephalopathy.

In August 1984 he was observed in a neurological unit where he was found to be incoherent, agitated and with a short attention span. He could not give his name or that of his wife, and denied that he had children. He was capable of obeying only simple commands, and co-operated poorly with neurological examination. No abnormal neurological findings could be detected, however, apart from a pout reflex and shuffling gait. The CT was unremarkable (Fig. 1). Repetition of the EEG, again with difficulty, showed only minor and non-specific abnormalities.

During September he deteriorated markedly, becoming increasingly depressed and regressed in his behaviour. The favoured diagnosis remained Ganser's syndrome, possibly on the basis of a depressive psychotic illness. Refusal to eat and increasing dehydration led to placement on a treatment order; four ECTs were given over the course of ten days, but without improvement.

In October 1984 he was referred for a further diagnostic opinion, the diagnosis lying between alcohol-induced brain damage, Ganser's syndrome or some form of presenile dementia. At this stage he was perplexed, gazing vacantly, and spoke a slurred incoherent babble. Formal testing of cognitive functions was impossible because of his extreme distractibility. Neurological examination revealed gross apraxia, generalised myoclonic jerks, choreoathetoid movements and a lurching unsteady gait. There was generalised hyper-reflexia and down-going plantar responses. He was incontinent of urine and faeces.

Apart from a mildly elevated serum glutamic-oxaloacetic transaminase level, biochemical investigations, including serum copper and leucocyte enzyme studies (arylsulphatase A, β-galactosidase and hexosaminidase), were normal. CT scan now showed some definite enlargement of the ventricles (Fig. 2). The EEG showed two distinct pictures: when relaxed and relatively immobile, alpha rhythm was apparent bilaterally with little by way of slow activity; when more active and with the eyes open, however, there was evidence of gross diffuse cerebral dysfunction with little alpha and prominent slow or very slow wave forms maximal over the left frontoparietal regions. There were no definite spikes, sharp waves or regularly repetitive wave forms typical of Creutzfeldt-Jackob disease or subacute sclerosing panencephalitis. Lumbar puncture proved to be impossible on account of the patient's lack of co-operation. Further investigations by way of jejunal or rectal biopsy to exclude Whipple's or Kufs' disease were considered unwarranted in view of his deteriorating physical state.

He was returned to his base hospital with a probable diagnosis of Creutzfeldt-Jakob disease and treatment with amantadine (300 mg/day) was prescribed. Despite this he followed a steadily downhill course until his death in March 1985. During the last few months of life there were episodes of marked involuntary jerking movements, and also occasional tonic-clonic generalised convulsions.

Necropsy findings

The body was that of an emaciated man looking much older than his real age of 39 years. Extensive bed sores were present. The immediate cause of death was an inhalational bronchopneumonia; other internal organs were normal.

The brain weighed 1260 g. After fixation in formalin for 4 weeks, it gave the external impression of severe generalised atrophy with focal areas (frontal lobes and anterior left temporal lobe) of severe shrinkage atrophy. Large tissue blocks were taken of all cerebral lobes, the internal nuclei, the brainstem (in five places) and both cerebellar hemispheres. There was a profound spongiform encephalopathy with intense fibrous gliosis seen in the frontal, parietal, occipital and temporal lobes, in decreasing order of intensity. The internal cerebral nuclei, brainstem and spinal cord showed minor degenerative changes, chiefly gliosis, but no spongiform change. Minor spongiform change with gliosis was seen in the cerebellum.

In summary, the neuropathological findings confirmed the diagnosis of Creutzfeldt-Jakob disease and excluded other major causes of dementia such as Alzheimer's disease, Pick's disease, cerebrovascular disease, tumours and obstructive hydrocephalus. Unusual features were the marked focal atrophy, the only slight involvement of the cerebellum and the intensity of the fibrous gliosis. This last feature is in keeping with the fact that the course of the illness was longer than is commonly seen.

Discussion

Several confounding factors stood in the way of early diagnosis in this patient. Firstly, the history of excessive alcohol intake clouded appreciation of the significance of his early memory difficulties, leading to tentative diagnoses of Korsakoff's psychosis or other alcoholic encephalopathy. It remains possible that the presence of underlying brain pathology made him unduly susceptible to the effects of alcohol on memory, or conspired towards the escalation of his drinking prior to referral. Secondly, the difficulties in the marital situation could readily be construed as leading to depression or more directly to a state of pseudodementia. The variability of his cognitive impairment, not unusual in early Creutzfeldt-Jakob disease, reinforced this last impression, resulting in diagnoses of hysterical pseudodementia or Ganser's syndrome.

Of more general applicability were the difficulties raised by investigatory procedures. The finding of a normal CT scan well into the illness, and the inconsistent EEG changes, proved unhelpful in arriving at the correct diagnosis. Interestingly, both the later EEG and an earlier one showed abnormalities in the left temporal and frontal regions, correlating with the marked left temporal atrophy seen at autopsy.

The important general lesson must remain that a dementing process such as Creutzfeldt-Jakob disease needs to be seriously considered in any patient with progressive cognitive impairment, even though the clinical picture shows remarkable variability and the CT scan is normal. Effort directed towards careful serial EEGs and repetition of the scans could then be important in yielding clues to earlier diagnosis. A related point is the need to suspect such a process even in the presence of an alcoholic history when the course and clinical picture do not behave as would be expected in an alcoholic-related illness.

Capgras Syndrome – An Unusual Case and Discussion of Psychodynamic Factors

A case of Capgras syndrome associated with extreme violent behaviour is described. The patient's psychodynamics support the belief that the Capgras delusion initially arises from an altered affective response towards one or more others and proceeds to intolerable ambivalent feelings. This ambivalence is neutralised through the imagined existence of doubles.

It is more than 60 years since Capgras & Reboul-Lachaux (1923) first reported the case of a patient with an 'illusion of doubles'. Their patient was a 53 year-old woman who had a delusional belief that people in her life had been replaced by doubles, and that she herself had a double. In an extensive review of the Capgras syndrome, Berson (1983) confirmed that the belief in the existence of doubles of others is frequently accompanied by a belief in the existence of a double of the self.

Originally the syndrome tended to be viewed as a single nosological entity, but it is now recognised that the central delusion is seldom seen in isolation. Merrin & Silberfarb (1976) reviewed 46 cases, 28 of which were diagnosed as schizophrenic. The majority of the 133 cases reviewed by Berson (1983) also had schizophrenia, particularly paranoid schizophrenia. The syndrome is also seen, however, in association with paranoid states and with both depression and mania.

Vié (1930) proposed that the Capgras syndrome was an organic psychosis. Many other authors have described the disorder in association with a wide range of organic brain disease; McCallum (1973) described five such cases. On the other hand, Kiriakos & Ananth (1980) examined 13 patients with Capgras syndrome, but found organic changes in only four.

Various authors have pointed out that the Capgras syndrome would be more appropriately named the Capgras symptom, i.e. a delusion of doubles. It certainly should not be regarded as a diagnostic entity in itself.

We describe here a patient with the Capgras syndrome associated with extreme violence. The relevance of some unusual features to the current psychodynamic theories of the Capgras delusion is discussed. It is not, however, suggested that psychodynamic factors actually cause a delusion; psychodynamic factors can account for the content of a delusion, but not its occurrence.

Case report

Mrs M was a 47 year-old divorcee, first seen by us when admitted to the forensic unit of a provincial psychiatric hospital in Canada. She was born in a small town, the oldest of four siblings. Her father worked as a motor mechanic and her mother as a housewife. There was no evidence of psychiatric illness in either branch of the family. The patient described her early childhood as relatively happy and uneventful until the age of eight, when her father started to drink heavily and to womanise. There was considerable disruption of her parents' relationship at this stage. Mrs M began to have nightmares, and at school was nervous and frightened of her teachers. Although her father continued drinking through her high school years, Mrs M appeared to be better adjusted, having a group of female friends and taking part in the usual adolescent pursuits, including dating. Educationally, she attained grade 12 and left school at the age of 19 to work as a typist and secretary.

At the age of 23 Mrs M had a six month courtship, during which she became pregnant. She had already experienced one psychotic breakdown by that time, and she stated that she married in order to avoid readmission to a psychiatric hospital. After her marriage Mrs M worked as a housewife. The couple's relationship was stormy; at the time of presentation Mrs M had been separated from her husband for five years and divorced for two years. She had a daughter and son by her husband, aged 23 and 16 respectively, and an illegitimate child who was born one year after her son and adopted away at birth.

Mrs M was first admitted to hospital at the age of 22, at the start of her illness. The onset was characterised by a conviction that her real father went off to Korea and that an almost identical double came into the house to take his place. She had 11 subsequent admissions to psychiatric hospitals, and had been an in-patient in another hospital for four continuous years prior to her transfer to our unit. Mrs M had been chronically deluded since her illness began and required a lot of psychiatric support, even when she was an out-patient. She had been consistently diagnosed as suffering from paranoid schizophrenia.

It was apparent from case-notes that Mrs M's psychopathology remained little altered throughout the years: the delusion of doubles had always been central. Her father, sisters, and husband, her two legitimate children, nursing staff, and other patients had all been replaced by doubles at one time or another. In the case of her son and daughter she reported the existence of multiple doubles who frequently interchanged at various times during their lives. She believed that she had the ability to distinguish between these various impostors by minor physical differences, such as height, skin texture and length of nose; this is typical of patients with the Capgras syndrome. Mrs M believed that some of the original people had disappeared permanently. She reported that her father had never returned from Korea and that her real daughter had been murdered at the age of seven. In contrast, most of the other doubles alternated with the original people they were impersonating, although sometimes the originals remained absent for long periods of time: "My son went off to explore the world when he was a toddler, only returning home a few years ago".

It has been suggested that the Capgras syndrome is only manifested towards people with whom the patient has a strong emotional attachment. In fact, in the case originally described by Capgras & Reboul-Lachaux (1923) this is not so, and our patient also attributed doubles to many people whom she knew only slightly. For example, she had only been on our unit for one month when she stated that one of the male nurses had a double, and she also believed that one of the authors had a double who had intentions of murdering her daughter. Mrs M also reported that on one occasion, ten years previously, she had seen a double of herself while in another psychiatric hospital. This experience only lasted a few moments and was not repeated, but she still believed in the existence of this 'self-double'.

A consistent and fascinating phenomenon was her delusion of part-replacement: she reported that she had been aware for some time that a number of her bodily organs had been removed during the night and replaced by those of other patients. This conviction started with her awareness of an altered internal sensation, and eventually she perceived this to be the result of replacement of her organs. She stated that this involved an operation through her vagina, thus enabling the organs to be exchanged without leaving a scar. Her vagina, uterus, ovaries, liver, heart, stomach, and brain had all been exchanged at some time or other. Occasionally messages arose from these organs, which often indicated their source of origin. Some months prior to her admission to our unit a voice came from her stomach saying that it was going to kill her son. She felt that this was not her own voice, and then suddenly realised that the stomach belonged to another patient and must have been exchanged for her own while she was sleeping.

Mrs M demonstrated the unpredictability of some chronic schizophrenic patients. She had been chronically deluded, despite high-dose depot injections of phenothiazines. Through the years she had intermittently expressed aggressive and homicidal threats towards her family and fellow patients in various hospitals. At home there were occasional episodes of violence; when her eldest son was two years old she injured him by throwing him against a wall, and on another occasion she attacked her sister with a knife. In hospital, aggressive behaviour had been an intermittent problem, although she had not inflicted serious injury on any occasion.

In the months before her admission to our unit, Mrs M had remained relatively well. Though still deluded, she appeared to be functioning at a socially acceptable level, displaying neither overtly aggressive or threatening behaviour. In the week prior to her transfer she became convinced that another patient on the ward (Mrs V) intended to murder her "daughter's double". Mrs M believed that it was Mrs V who had murdered the "original daughter" 16 years previously, and also believed (incorrectly) that Mrs V was about to be discharged from hospital. She came to the conclusion that the only way to save her daughter was to kill Mrs V. She ruminated on this for two days and then, while on a pass from the hospital, procured a large knife from a local shop, which she smuggled into the hospital. During the night she entered Mrs V's bedroom and, while the patient slept, she cut her throat, killing her outright.

At her trial Mrs M was found not guilty by reason of insanity. It was accepted that she felt the killing of this fellow-patient was justified and morally correct, on the basis of her delusional beliefs. She was ordered to be detained in a secure forensic unit.

Discussion

This case report sheds further light on psychodynamics of the Capgras syndrome. From our interviews with Mrs M it was clear that she had intense and ambivalent feelings towards a number of her family. She strongly resented her father's alcoholism and womanising, which disrupted the family stability. In her early twenties Mrs M experienced an early schizophrenic disintegration. It would appear that the intrapsychic regression that resulted allowed her to mobilise the primitive defence mechanism of splitting: the 'good father' was seen to be replaced by a double for whom she could more acceptably harbour aggressive feelings.

Such dynamics have been suggested previously to explain the Capgras delusion. Capgras himself, in relation to two cases, referred to feelings of strangeness (Capgras & Reboul-Lachaux, 1923; Capgras *et al*, 1925). Others (e.g. Berson, 1983) have expanded on this idea, suggesting that people become aware of changes in their usual affective responses to significant others and attribute these changes to changes in the other person. We might term this a 'projected depersonalisation'. Our patient demonstrated a similar phenomenon in relation to her somatic delusions. She reported initially experiencing a change in her internal sensations, and then assumed that these were not her own bodily senations: "There was a strange sensation from my vagina and I knew it was not mine, as mine had never felt like that. I then realized it had been exchanged during the night for somebody else's". The replacement of various internal organs appears to be in effect a partial Capgras delusion with respect to herself.

Mrs M also had hostile feelings towards her daughter. These may have been associated with her unexpected conception, which forced the patient into an unwanted marriage. By employing the defence mechanism of splitting, she was able to experience these feelings as being directed at an unrelated double. Presumably even this defence mechanism did not allay her anxiety, and she then projected her homicidal wishes onto a number of people, including her psychiatrist and Mrs V, all of whom she accused of wanting to murder her daughter. Mrs M then exhibited a gross reaction formation, destroying the person she perceived as wanting to harm her daughter. This had the incidental effect of sublimating her own homicidal impulses. Two pieces of evidence support this formulation. Firstly, Mrs M was in a state of calm on admission to our unit, only 12 hours after the homicide. She stated that there was no further threat to her children, even though she had believed that a number of other patients in her previous hospital had harboured similar feelings. Secondly, she had demonstrated projection of homicidal feelings previously, when she experienced the voice originating in her stomach which spoke of killing her son. On that occasion she denied ownership of the stomach and voice, ascribing both to another patient.

Conclusions

Apart from the presence of the Capgras syndrome, this patient resembles many chronic psychotic patients in long-stay hospital wards. It is worth bearing in mind that even chronic delusions can suddenly become invested with a high emotional charge, and that these patients can still act on their delusional beliefs. Chronicity reduces the likelihood of dangerousness, but it is not a guarantee against its occurrence.

This case supports the view that the Capgras syndrome is assocated with strongly held ambivalent feelings towards other people and is characterised by the use of the primitive defence mechanism of splitting, to defend against those feelings. Employment of splitting is probably secondary to an internal affective change, which is then projected onto the other person.

Hostility and Deliberate Self-Poisoning

Sɪʀ: May I draw attention to another concept of 'hostility', additional to those covered by Farmer (*Journal*, May 1987, **150**, 609–614). This is the concept of irritability. Farmer supplies four descriptions of factors covering the construct of hostility: aggression, attitude of dislike, anger, and a predisposition to behave in a hostile or aggressive manner. The concept that we introduced (Snaith & Taylor, 1985) is that of irritability and, at our request, this was accepted as a new Medical Subject Heading, under the term 'Irritable mood', in the *Index Medicus*. In order that the term might be used in a standard way we supplied a definition: "Irritability is a feeling state characterised by reduced control over temper, which usually results in irascible verbal or behavioural outbursts, although the mood may be present without observed manifestation. It may be experienced as brief episodes in particular circumstances, or it may be prolonged and generalised. The experience of irritability is always unpleasant for the individual and overt manifestation lacks the cathartic effect of justified outbursts of anger".

Our interest in this state had been aroused by Pitt's (1968) observation of its frequency in the setting of post-natal depression, and our own research into mood disorder following childbirth led to the development of a brief self-assessment scale, the Irritability Depression and Anxiety (IDA) scale (Snaith *et al*, 1978). The article introducing that instrument described how we also had looked at the Buss-Durkee, the HDHQ, and other instruments but found that none fitted the state which we wished to delineate. The IDA scale has two irritability sub-scales (the outwardly-directed and the inwardly-directed irritability scales) and these, together with the depression and anxiety sub-scales, were published in the original article in order that they may be freely used – subject only to acknowledgement of copyright to *The British Journal of Psychiatry* (a convenient form with incorporated scoring device is available free of charge on application to myself). The first of our papers quoted above presents the validation of these sub-scales in four different studies and it was concluded that the outward-irritability scale is a homogeneous scale but that the inward-irritability scale is composed of two concepts; two of the four items composing it relate to suicidal self-harm and the other two items to a more general feeling of annoyance with oneself. If the IDA scale is to be used in research in the setting of suicide studies it is now advised that the inward-irritable scale is analysed by these two separate components.

Farmer has drawn attention to the diffuse concepts covered by different measuring instruments. We maintain that the IDA scale, with the modification just referred to, does provide a simple, acceptable set of measures and we hope that others will use it in suicide studies as well as all the other psychopathological and other states (such as post-natal depression, head injury, epilepsy, and drug withdrawal) in which the two aspects of irritability are a common and troublesome feature.

Self-Poisoning and Suicide Attempts by Burning

Sir: The use of the term suicide 'epidemic' is fashionable. Both Farmer (*Journal*, May 1987, **150**, 609–614) and Zemishlany *et al* (*Journal*, May 1987, **150**, 704–706) use the term, in the former article to describe incidence trends in the general population, and in the latter to focus on the timing of three suicide attempts in a psychiatric hospital.

One should ask whether the 'epidemic model' of suicide is the appropriate concept for the phenomena being described. Strictly speaking, such a model would require the criteria of an epidemic, such as the identification of a 'host', a 'vector', and a 'mode of transmission' of a 'noxious agent', to be fulfilled.

Currently, there appears to be a resurgence of research interest in the 'Werther effect', referring to the phenomenon where newspaper publicity of suicides is apparently associated with an increase in suicide rates (Phillips, 1974). Phillips coined this term 200 years after Goethe's romantic novel *The Sorrows of the Young Werther* was banned in a number of centres in Europe for allegedly providing a model for imitative suicides. Some caution needs to be exercised in the labelling of increased suicide rates or of suicide clusters as "epidemics". Implied in the designation of a suicide "epidemic" based on imitation are preventative measures (such as the literary censorship that befell Goethe's novel), one being the suggestion that "educators, policy makers, and journalists may wish to consider ways of reducing public exposure to stories, both general and specific, about suicide (Phillips & Carstensen, 1986). While this recommendation may have superficial appeal, and may eventually be based on experimental evidence, the imitative propagation hypothesis to explain national suicide rate increases still awaits replicable proof.

Turning to suicide clusters, suggestible individuals, whether 'normal' young people or vulnerable adults in institutional settings such as hospitals or prisons, are more likely to be influenced by the basic psychological process of identification than by suggestion or imitation (Halasz, 1987) and the recommendation of "group sessions after a suicidal case in order to neutralise the identification with the act by suggestible patients" (Zemishlany *et al*) seems a clinical imperative.

However, this is a clinical recommendation, not in need of an epidemic model of explanation. Rather, it underlines the need for clinicians to recognise individual vulnerability in normal developmental phases, as occurs in childhood and adolescence, as well as in stress-induced regressed adult states brought about by illness, or dramatic changes in personal degrees of freedom.

No Fixed Abode

Sir: We read with interest the recent report by Herzberg (*Journal*, May 1987, **150**, 621–627). We compared four groups of patients: urban fixed abode, urban 'no fixed abode' (NFA), and rural and semi-rural consecutive male psychiatric admissions, with 50 patients in each cell (O'Shea *et al*, 1983). This study also used retrospective case-note information.

Poor employment records and early parental separation were common in the NFA group; rural men generally live with others, the homeless tend to be single (NFA: married, 3; single, 40; separated, 6; divorced, 1; widowed, 0); age did not differentiate any of the groups; all groups shared 'chronic schizophrenia' and 'alcoholism' as the chief diagnostic categories; the strong impression was gained that alcohol-related difficulties were generally underestimated; patients in the NFA group were more likely to have legal records; standard diagnostic methods were hardly ever employed; physical pathology was common and widespread in all four groups; routine ancillary tests were not readily available; and most patients came from the lower socioeconomic levels of society.

Specifically, the physical findings among the NFA group were: eight men had chronic obstructive airways disease, mostly with acute exacerbations at the time of admission; three, one with a past history of cerebrovascular accident, were hypertensive, and all of these were on hypotensive drugs; the man with the stroke had a residual hemiparesis and epilepsy; two other cases had experienced alcohol-related convulsions; a fourth man's fits were found to be due to an inoperable glioma; one alcoholic was unable to walk because of peripheral neuropathy; one hypertensive patient had angina pectoris, another was diabetic, and a third required surgery for varicose leg veins; six men had anaemia of nutritional origin – one had undergone sub-total gastrectomy 30 years previously; one young patient had a marked strabismus; three men had had duodenal ulcers, two having received surgery for this; two had a history of hepatitis; and five had received anti-tuberculosis chemotherapy within five years of admission. Ten of the NFA patients were grossly obese.

The finding of a high physical morbidity among *both* urban groups is in keeping with other reported work (Feldman *et al*, 1974). The fact that all four groups shared this unenviable record is most likely related to the fact that they had psychiatric illnesses (Cutting, 1980; Sims, 1978; Sims & Prior, 1978).

Late Paraphrenia or the Paraphrenias

SIR: Holden (*Journal*, May 1987, **150**, 635–639) perpetuates the confusion surrounding paranoid states in the elderly. A major contribution to this has to be the continuing reluctance to-diagnose schizophrenia arising for the first time in patients over the arbitrary age of 40 or 45.

Holden appears to be using the term 'late paraphrenia' in a very broad sense, including within the definition all cases of paranoia arising *de novo* after the 60th birthday. This is not in keeping with the clear definition of Kay & Roth (1961) he quotes.

I suspect that the 'organic' group could have been identified at the time of the initial contact, and it may be that the Gresham Ward Questionnaire is not sensitive enough to identify clinically important levels of poor cognitive function. It is interesting to note that the 'organic' group comprised 35% of the final sample, a figure not dissimilar to Post's "up to 30%". Paranoid symptoms are well known in patients suffering from organic brain syndromes (Ballinger *et al*, 1982) and the poor prognosis for organic brain syndromes has been known for some years (Roth, 1955; Christie, 1982; Blessed & Wilson, 1982).

I cannot agree with Holden that the differences between the concepts of "late paraphrenia" (Kay & Roth, 1961) and "persistent persecutory states of the elderly" (Post, 1966) have not been clearly resolved. The title of the Kay & Roth (1961) paper should leave one in no doubt as to their view of late paraphrenia. My own review of the term (Grahame, 1982) concluded that late paraphrenia is one of the schizophrenias, and this was supported by a later clinical study (Grahame, 1984).

Holden's final paragraph is, for me, the most confusing and I cannot see how the data presented support such a conclusion. Organicity is important in the genesis of 'persistent persecutory states of the elderly' but not of 'late paraphrenia', which in my view is as homogenous a clinical syndrome as any known to psychiatry. After all, there is no dispute about schizophreniform psychosis secondary to, say, trauma in young patients and the functional schizophrenias. The fact that some patients with late paraphrenia subsequently develop an organic brain syndrome should not necessarily lead one to say that the late paraphrenia was a symptom of an organic brain syndrome. Just over 40% of patients in the Blessed & Christie (1982) study had an organic brain syndrome, and they comment that their findings "again lend little support to the idea that functional illness in old age is the harbinger of senile or arteriosclerotic psychosis". Inspection of Table I of Blessed & Wilson (1982) shows what they consider late paraphrenia to be.

Finally, had Holden interviewed his patients using the Geriatric Mental Status Interview, he may well have found more patients reporting first rank symptoms which, in turn, may have had a significant effect on his final groupings.

Comparative Trial of a New Antidepressant

SIR: There are 16 tricyclic and related antidepressants currently on the market. It seems likely that most psychiatrists use only a small number of them routinely. Before any more new antidepressants are added to this list, how insistent should we be in requiring that standardised methodologies be employed when testing their efficacy?

Levine *et al* (*Journal*, May 1987, **150**, 653–655) showed that fluoxetine was as effective an antidepressant as imipramine. However, their study did not include a placebo control to establish the relative efficacy of both of these drugs. The reason for this not uncommon omission is that imipramine is considered to be of proven efficacy and, therefore, a reliable benchmark against which new antidepressants can be measured. How justified is this assumption?

In two extensive reviews of the literature, tricyclic antidepressants were not found to be superior to placebo in 35% (Morris & Beck, 1974) and 41% (Thomson, 1982) of studies. Swallowing an inert placebo leads to a significant improvement in between 30% (Morris & Beck, 1974) and 50% (Medical Research Council, 1965) of those suffering from depression. Mild side-effects (which fluoxetine possesses) are associated with greater drug success, while zero or severe side-effects are associated with less success (Brune *et al*, 1962). The advantage of tricyclic antidepressants over placebo is significantly less when an active (atropine) placebo is used instead of an inert substance (Thomson, 1982). Thirty per cent of depressed patients do not respond to tricyclic antidepressants (Medical Research Council, 1965): in the Levine *et al* study this figure was approximately 50%.

Thus the universal and invariable efficacy of tricyclic antidepressants has yet to be demonstrated. Therefore, imipramine and other 'standard' antidepressants should not be used as the sole agent in comparative studies. Levine *et al* did not use a placebo control, so we cannot be sure whether the improvement in depressive symptoms was due to a specific psychotropic, or an active placebo, effect.

Comparative Hospital Survey of Psychotropic Drug Prescribing

SIR: Muijen & Silverstone (*Journal*, April 1987, **150**, 501–504) showed that the hospital (hospital A) with the lowest prevalence of polypharmacy was the only one with an associated psychopharmacology unit. We have compared the authors' results with our acute in-patient population. Our data is obtained from a unit in our hospital, the population of which can be compared to that of the authors' hospital C. Ours is a teaching hospital, but has no association with any psychopharmacology unit.

Seventy-eight patients admitted in the past year were included in the study. All psychotropic drugs given on the seventh day of admission were recorded from case records; we presumed that a final diagnosis was reached and medication was started by one week after admission. The rest of our methodology is similar to that of the authors' study.

The results showed that more than one psychotropic drug was given to 49 patients (63%). This figure is close to the authors' figure for hospital A. More than two drugs were given to 23 patients (29%) and more than three drugs were given to 8 patients (10%). One patient received no drugs, one drug was given to 23 patients (29%), two drugs were given to 28 patients (36%) and three drugs were given to 18 patients (23%). Benzodiazepines were given to 22 patients (28%). More than one antipsychotic drug was given to 21 patients (27%), whereas antiparkinsonian drugs were given to 17 patients (22%). The last two figures are lower than the authors' hospital A figures. We conclude that drug prescription is more influenced by general training than by any association with a psychopharmacology unit.

Compulsory Detention of Males of Different Ethnic Groups

Sir: We wish to comment on the article by McGovern & Cope (*Journal*, April 1987, **150**, 505–512).

Since 1976 the Mersey Region has had a secure unit, initially in the form of an interim facility and since 1983 as a regional secure unit. The unit accepts referrals from special hospitals, prisons, remand centres and other psychiatric hospitals. Our clinical impression was that admission rates for patients of West African and West Indian descent were in proportion to their numerical size in our catchment population. In the light of the above study we examined our data relating to admissions for a defined part of our catchment area, in which patients in the category defined above make up 6% of the population.

Since 1976 there have been 93 admissions to our unit from the defined area (78 male and 15 female): 14 patients were of West African or West Indian descent. Of the 93 admissions, 63 were offenders and 30 non-offenders. Patients of West African or West Indian descent were over-represented among offenders (12/63) but not among non-offenders (2/30).

Our figures support the findings of McGovern & Cope. We are unable to account for these differences, but can say that our clinical experience does not support the suggestion that patients of West African or West Indian descent are more disturbed, violent, or difficult to follow-up in the community. We are currently planning a survey in a larger sample including special hospital patients.

The Psychological Well-Being of Supporters of the Demented Elderly

Sir: Two things puzzle me about the paper by Eagles *et al* (*Journal*, March 1987, **150**, 293–298). Firstly, it seems little short of miraculous that the 1980–1982 MSQ had 100% sensitivity, specificity, and predictive values with the 1983–1984 psychiatric assessment of the presence of dementia in the "dependants" of the first 80 supporters agreeing to the interview. It is not clear whether this represents a startling improvement in psychiatric epidemiology, or whether there is some more prosaic reason.

Secondly, why were the 'non-demented' elderly people in this survey being "supported" at all? It is likely from the way they were apparently recruited that they were having problems, but since the vast majority of 'non-demented' elderly people look after themselves perfectly well, there must have been something else going on here. This, rather than the explanations offered in the discussion, may explain why GHQ scores did not differentiate between the groups.

It is a pity that such elementary points of clarification could not be dealt with before the paper was published.

A. J. D. Macdonald

Community Team for Mental Health in the Elderly
Hither Green Hospital
Hither Green Lane
London SE13 6RU

Sir: Macdonald's puzzlement stems from his having misunderstood the methodology of our study. The MSQ carried out in 1980–82 allowed identification of a group of elderly patients who were living at home and were possibly demented, since their MSQ score was 8 or less at that time. These 205 subjects were matched for age and sex with 205 subjects scoring 9 or 10 on the MSQ. These subjects were then re-interviewed in 1983–84 with the aim of, among other things, assessing the follow-up validity of the MSQ. For the purposes of the present study, the 1980–82 MSQ was ignored and the ratings of the patients are those made during the psychiatrist's visit in 1983–84.

With regard to Macdonald's second point, the 'non-demented' people in this survey were not necessarily being "supported". We make it fairly clear that the criterion for their inclusion was that they were co-habiting with someone who was willing to complete our questionnaires, and that this co-habitee would bear the burden of support, if such support were necessary. I cannot understand Macdonald's contention about these patients that "from the way they were apparently recruited they were having problems". They were recruited solely on the basis that they were 'non-demented' elderly patients whose co-habiting relative was willing to answer questions about what problems, if any, they encountered in "supporting" the elderly person.

Concept of Mild Endogenous Depression

SIR: Unfortunately, Snaith's essay (*Journal*, March 1987, **150**, 387–393) is representative of most discussions about the use of the term 'endogenous' depression, being just another example of defining words by other words at the same level of abstraction.

When multiple clinical items of depression are aggregated, the resulting scale of categories can be arranged as a hierarchy. The hierarchical arrangement provides a clear idea of what is contained in the total scale score of the individual items. The most simple model for evaluating hierarchical aggregations is the Rasch model, because items here will obtain equal weights if they fulfil the model (Bech, 1981). Applying Rasch models on the universe of items defined by the Melancholia Scale and the Newcastle Scales (Bech *et al*, 1983), we have found one dimension of severity of depression and two dimensions for the diagnostic type of depression (Bech & Allerup, 1987).

In total, 11 items constituted the dimension of severity, which in increasing hierarchical order are: difficulties in carrying out usual work; lack of interests and pleasure; reduced sleep; more apprehensive or irritable than usual; more emotionally introverted than usual; difficulties in concentration; more tired than usual; self-depreciation or guilt feeling; pronounced inertia in conversation; clear motor retardation; and suicidal thoughts or impulses.

In relation to the two diagnostic dimensions, we found that five items constituted endogenous depression: persistence of clinical picture; weight loss; early waking; worse in the morning; and distinct quality. Another five items constituted reactive depression: duration of current episode; somatic anxiety; character neurosis; reactivity of symptoms; and psychological stressors.

According to these dimensions we can classify patients into minor or major depression and diagnostically into endogenous or reactive depression.

The state of anhedonia described by Snaith is nothing more than mild endogenous depression. 'Anhedonia' is traditionally used to describe the borderline personality who suffers from a painful lack of vitality based on a narcisistic distance from other people. According to Vanggaard (1979): "Not infrequently this anhedonia is called 'depression', and this is erroneous. An anhedonic state is a far cry, phenomenologically and theoretically, from a depressive one, as different as the general personalities of persons harbouring such states, if the terms are properly understood and used".

From a psychopharmacological point of view anhedonia should be treated with neuroleptics, whereas mild endogenous depression should be treated with antidepressants. Patients who do not respond to antidepressants should be diagnostically reconsidered, as they might be borderline cases.

Tuberous Sclerosis and the Autistic Syndrome

SIR: I was surprised to read that Lawlor & Maurer (*Journal*, March 1987, **150**, 396–397) believe tuberous sclerosis (TS) to be a rare cause of the autistic syndrome. Parents of children with TS have known otherwise for some years, and child psychiatrists, paediatricians and others have been made aware of it more recently. Lawlor & Maurer fail to point out that the autistic syndrome is closely linked to the early occurrence of *infantile spasms* (Kolvin *et al*, 1971, Hunt & Dennis, 1987) and, much less so, to other forms of epilepsy.

The point I wish to make is that TS is not as rare as was once thought. In the Oxford Region in 1984, the prevalence was 1 in 15 400 for children under five. Children with TS do present at departments of child psychiatry from time to time, and I support the conclusion of Lawlor & Maurer that a high index of suspicion should be maintained when confronted with an autistic child who has fits – but also, I would say, when assessing hyperkinetic, aggressive, and sleep disordered children with fits. Furthermore, in my experience, the diagnosis of TS has been made in children who show the behavioural disorders but who have never had a fit.

Delusional Infestation in Late Life

SIR: Renvoize *et al* (*Journal*, March 1987, **150**, 403–405) provide a useful review of the literature, including the German literature, in reporting their interesting patient whose delusions of infestation occurred during the course of a dementing illness. We have been interested to find that delusions of infestation are seen quite commonly among the patients referred to our psychiatric services for the elderly and we recently reviewed seven cases that presented between 1983 and 1986. There were two men and five women. Their ages ranged from 69 to 76 – a little above the boundary of 'late middle age', the age-group from which patients are most frequently reported, but not very old (patients aged 75 and above constitute about three quarters of our referrals).

All seven were found to be depressed. None were seriously demented, although in three there was clear evidence of some organic cerebral impairment and in only one could we be sure that there was no such pathology. In two patients the delusions of infestation developed in the context of guilt at not maintaining cleanliness in the home after the death of a spouse. In three, previous neurotic preoccupation with cleanliness or 'phobia' of 'creepy-crawlies' had become delusional in the setting of severe depression, and in the last two the delusion was part of a systematic belief that the body was changed and degenerating.

In most of our patients the delusions appeared when powerful change of affect occurred with mild organic change. This is a potent combination in the genesis of delusions (Hay *et al,* 1974). Successful treatment of the mood disorder has led to resolution of the delusions of infestation in the six cases we have known longest. Thus, in this age group delusions of infestation may be less persistent and pernicious than those of the monosymptomatic psychoses that are reported more commonly in younger middle-aged patients. The presence of some organic impairment should not detract from the treatability of the condition through an appreciation of the mood disorder.

Hysterical Personality Disorder

SIR: Thompson & Goldberg (*Journal*, February 1987, **150**, 241–245) question the validity, reliability, and utility of the diagnosis of hysterical personality disorder. Though such issues are properly raised about a vexing construct, I believe the authors' gloomy conclusions may not be wholly warranted.

Based on a retrospective review of case notes, Thompson & Goldberg observe that the diagnosis "is frequently made without the core features being present". Their finding may tell us less about the construct, hysterical personality disorder, than it does about diagnostic practice and documentation at Withington Hospital in 1975. Had the authors tabulated the "core features" present in the case notes of patients with another diagnosis we would be better able to judge where the problem lay.

This matter is of considerable importance because the authors fear that the diagnosis of hysterical personality disorder may be used "to label those patients who are perceived as hostile, difficult, and uncooperative, with the result that the doctor is distracted from recognising an underlying diagnosis". Prominent among such proposed underlying conditions is 'primary affective disorder', which the authors claim that McHugh and I found (Slavney & McHugh, 1974) in a sample of patients with the diagnosis of hysterical personality disorder. I feel constrained to point out that what we noted was not 'primary' affective disorder, but rather the frequent occurrence of depressed mood and self-injury, phenomena which we interpreted as the responses of self-dramatising and emotionally labile people to stressful circumstances (i.e. as 'secondary' to events such as romantic disappointment). What was 'underlying', then, was the personality disorder, the recognition of which a psychiatrist should not be distracted from by the presence of affective symptoms. The validation of the trait of self-dramatisation has yet to be accomplished, but there is some support (Slavney & Rich, 1980) for the existence of emotional lability as an actual attribute of patients who receive the diagnosis of hysterical personality disorder.

Finally, the authors observed low inter-rater reliability in the assessment of hysterical traits based on brief videotaped interviews. The diagnosis of personality disorders in the clinical setting, however, depends to a great extent on the description of patients by those who know them well, and recent developments in the standardised assessment of traits as rated by informants gives hope that diagnostic reliability can be improved. Using the scale devised by Mann *et al* (1981), for example, Ballinger (1987) has recently shown acceptable inter-rater reliability in the rating of traits (including hysterical ones) for a sample of patients with mental handicap. As well as this, there is evidence to suggest that judgements about the central trait in the hysterical cluster – self-dramatisation – are not greatly influenced by the sex of the rater or by the sex of the patient (Slavney & Chase, 1985).

Thompson & Goldberg call our attention to important matters, but not to lost causes.

SIR: Our conclusions are far from gloomy. We draw attention to a group of patients whose response to illness, whether physical or psychiatric, is characterised by difficult, demanding, and aggressive behaviours. Our findings should encourage clinicians to properly examine such patients for underlying illness and not attribute their behaviours and symptoms exclusively to personality disorder. We contend that the recognition of such underlying illnesses in patients affords a greater opportunity for effective treatment than would be the case if they were to be managed simply as 'personality disorders'.

We concede that our data reflects the clinical practices at Withington Hospital, but we have worked in a variety of hospitals in the UK and would describe the practices at Withington Hospital as similar and certainly no worse than those in other hospitals. One author (DG) has also worked in several hospitals in the United States and observes that the particular clinical practices there are comparable. In Slavney & McHugh's (1974) paper comparing hysterical personality disorder with control patients, the only criteria that referred to the mental state and significantly distinguished between the two groups were the items "dramatic" and "change of therapist". The latter suggests those same behaviours that characterised our index group. Core features such as provocativeness, seductiveness, and lability of mood were not significantly different.

The theme which we consider central is the relative role of illness and personality. The evidence suggests that personality traits may be exagerated by major stress, and that may include an underlying physical or psychiatric illness. The personality disorder simply colours (or sometimes clouds) the presentation as seen by the doctor. To say otherwise ignores evidence amassed from follow-up studies in a variety of hospitals, almost all of which demonstrate a high level of unrecognised illness at the index episode (Slater, 1965; Reed, 1975).

Capgras' Syndrome in a Patient with Dementia

SIR: I describe a further patient (Kumar, *Journal*, February 1987, **150**, 251), with the additional feature of prominent visual hallucinations.

Case report: An 86-year-old man was referred with a six-month history of believing his wife was replaced by an imposter every afternoon – during which time his real wife (78 years old) was soliciting young men in local pubs. At the same time he regularly saw up to four young women in the house. He varied between being annoyed by their intrusion and being friendly towards them when he believed they had come to help with the house-work. On his wife's 'return' he would express anger at her behaviour. After some weeks he began making sexual demands of his wife, stating that he was entitled to his 'share'. He was then distressed by his failure to achieve an erection. Since the couple's sex life has been in abeyance for years his wife made clear her fears for his physical health, which made him even angrier. He threatened her with a stick on a number of occasions. One night he tried to cut off her pyjamas with a pair of scissors, and this led to his referral.

His wife described a three-year gradual decline in memory. Premorbidly, he was said to be a self-contained suspicious man, particularly distrustful of women. There was no psychiatric history. Two months prior to the onset of this episode he suffered a chest infection during which he suspected his daughter of trying to poison him. These beliefs resolved completely following antibiotic treatment. On mental state examination, the features were delusional misidentification, delusions of jealousy, visual hallucinations, and impairment of short-term memory without impairment of consciousness. He had no insight, and expressed anger towards the "imposter". He was quite deaf, but otherwise physical examination was normal. Routine blood tests were normal. A diagnosis was made of a paranoid syndrome secondary to dementia, probably of Alzheimer type. He was treated with thioridazine, up to 100 mg/day, with resolution of the Capgras syndrome and visual hallucinations.

This patient is of interest for several reasons. Firstly, he illustrates Enoch's (1979) theory of ambivalence towards the loved object revealing itself in the Capgras syndrome, but differs in that the sexual demands followed the onset of the Capgras syndrome rather than that the rebuffed demands contributed to the development of the syndrome. One could speculate that a lesion in the right occipito-parietal area might result in both visual hallucinations and Capgras syndrome following the suggestion (Haymans & Abrams, 1977) that facial non-recognition causes the Capgras syndrome. However, I would agree with the observation (Weston & Whitlock, 1971) that the Capgras syndrome is the exact antithesis of facial non-recognition, there being no difficulty in the patient recognising the imposter as a replica of the person concerned. Sensory deprivation (Gluckman, 1968) has been mentioned as relevant; and this man's deafness, in conjunction with living close to a noisy girls' school, might be important aetiological factors.

Trazodone-induced Mania

SIR: Knobler *et al* (*Journal*, December 1986, **149**, 787–789) report on three cases of trazodone-induced mania. Two of their patients had DSM–III mixed bipolar disorder, and the other had DSM–III recurrent major depression. I would like to report a case of trazodone-induced mania in a patient with a single episode of major depression.

Case report: A 58-year-old female widow met DSM–III criteria for major depression with melancholia (296.23) (single episode). She had suffered from depression for two years. Examination revealed depressed mood and affect, hopelessness, anhedonia, transient suicidal ideation, loss of energy and interests, loss of appetite and weight, and insomnia. She had no previous affective or other mental disorders. Her brother was a schizophrenic and committed suicide. Treatment (out-patient) with trazodone (50 mg t.i.d.) was started. In two or three days her mood was less depressed, and she felt better. But after one week of treatment, she became very talkative, quarrelsome, sleepless, hyperactive, and restless. She was spending money uncritically and frequently changed her clothes. She also thought that her grand-daughter had been poisoned by her son-in-law. She was admitted to hospital.

On admission she showed pressure of speech, psychomotor agitation, and mood-incongruent delusions. Trazodone was stopped, and treatment with haloperidol (1.5 mg t.i.d.) was started. After one day, her delusions completely disappeared and her mood was less elated. On the next day she was transferred to a general hospital because of paroxysmal tachycardia. There she was found to have hyperthyroidism and ischemic cardiomyopathy. She was seen after one month as an out-patient: her mood was stable and haloperidol treatment was stopped. After three weeks she was seen again, and she was in remission.

A causal connection between trazodone treatment and the manic state in this patient seems obvious. Her manic episode started only a week after trazodone was prescribed, and this was her first manic episode. She received trazodone without any other psychotropic medication. After the discontinuation of trazodone the manic episode remitted in less than ten days.

The mood-incongruent delusions in this patient are confusing. They were of short duration (about three days), but represent a difference between the patients described by Knobler *et al* and this patient. The patient's family history of schizophrenia may be relevant. The patient's hyperthyroidism could have some aetio-pathogenetic role in the depressive episode, but this is less likely in the sudden mood change to mania. Our patient was probably hyperthyroid for more than one year (according to the medical history and findings). She had had no mood up-swings until the trazodone treatment began. If the manic state was triggered by hyperthyroidism one would have expected its manifestation earlier.

Long-Term Psychiatric Patients In The Community

Sir: Kathleen Jones and her co-workers (*Journal*, November 1986, **149,** 537–540) paint an optimistic picture of care in the community in York when documenting the fate of 50 long-term psychiatric patients discharged into the community. They suggest that similar surveys in other areas might have less favourable results.

We conducted a follow-up of all patients who had been in Banstead Hospital continuously for at least 2 years and were subsequently discharged into the community between 1970 and 1981. There were 25 such patients.

The majority had led surprisingly stable lives since discharge (average 6.25 years). Readmission rates to hospital were low. All but one patient remained out of hospital, and only four others had been readmitted for brief periods. Half the patients had lapsed contact with the psychiatric services, but of these, half still had regular contact with their GPs and received depot medication. One patient was unfortunately in prison for aiding and abetting rape, and four had died of natural causes at an advanced age.

We assessed the quality of life of the patients by interview with the patients and their carers using a semi-structured interview. The patients fell into two groups of roughly equal numbers. The first group was made up of those with few if any symptoms, a low dependence on psychiatric services, and an ability to lead active independent and generally contented lives. These were primarily schizophrenic patients living in high quality group homes. The second group consisted of those with some degree of symptomatology, receiving a higher degree of support from psychiatric services and having a tendency to live more passive, dependent, and somewhat discontented lives.

Our findings support the view that community care with appropriate resources is a viable option for selected long-stay hospital patients.

Erotomania and Cerebral Dysfunction

Sir: *Case report:* Recently a 30-year-old right-handed patient presented with erotomania of the de Clérambault's type and somatic delusions. Two years ago he met a 16-year-old salesgirl, felt it was love at first sight, and thereafter believed that she communicated a mutual love by means of silent gestures, ringing in his ears, telepathic messages, chain letters, and cars driving past him; he believed that she attempted to make him jealous by having sexual relationships with countless men. He had previously held similar beliefs about two other women. Over the same period he had somatic delusions, experiencing a number of physical symptoms that he attributed to the influence of this woman.

The patient had depressed mood and a large number of neuro-vegetative symptoms when these delusions were at their height, but had recovered by the time he was seen. He had made a suicide attempt in the past, had a history of heavy alcohol abuse ending four years previously, and had a family history of affective disorder. On examination he was mildly elated with rapid, pressured speech; verbal fluency was poor, he was unable to do an alternating hand sequence, and he showed verbal-motor dissociation on the right with the Luria hand sequence. The EEG showed left temporal abnormalities. The symptoms abated slightly with pimozide; the patient refused lithium and carbamazepine.

Erotomania has been reported with frontal and left temporal lobe dysfunction with secondary mania (Signer & Cummings, in press); the latter has shown a particular association with delusions (Sherwin *et al*, 1982). The EEG showed left temporal, and the cognitive examination left frontal, dysfunction. With appropriate examination and investigation more patients with erotic delusions may be shown to have organic abnormalities requiring specific treatment.

Italian Psychiatry

SIR: Most articles dealing with Italian psychiatry in the past five years have considered the public sector side of psychiatric intervention, while omitting any comment on private practice (Mosher, 1982; Becker, 1985; Jones and Poletti, 1985, 1986; Tansella, 1985).

The regulated, public sector is carefully analysed by the above authors, but it may be helpful to underline a trend towards a further splitting of psychiatric practice. In the public sector there is an area, i.e. acute control/therapy, which can be considered as strictly medical (it includes psychiatric wards in general hospitals and mental health centres); now, a second area is under development, i.e. long-term assistance/surveillance, which is to a great extent de-medicalised. This area includes day hospitals and criminal psychiatric hospitals.

In the acute control/therapy area psychiatrists see acute patients who respond to treatment. In the long-term surveillance/assistance area there are mental health workers, most of whom are psychologists and sociologists, who stress their rehabilitation role in relation to patients' (possible) readmission into society. There is a long-running dispute between the two groups about the relevance of medical or sociological attitudes towards patients with mental disorder. Psychologists (who use the language of psychoanalysis and anti-psychiatry) are trying to take over, particularly in those regions, like Veneto, where there is already a good level of long-term assistance. The gradual worsening of public health standards, and the fact that psychiatry is poorly regarded in medicine, do not allow a debate and a comparison of results on purely technical grounds.

Moreover, in the private de-regulated sector psychotherapies and psychopharmacological treatment have flourished in an uncontrolled way. Here too the field is splitting asunder: the former being the province mainly of psychologists, the latter of psychiatrists. Patients have great difficulty in finding reliable help in the private sector, (although, of course, they pay for services) as recent legal actions testify. While admission to private clinics is still limited (at least in Northern Italy), such interventions are likely to increase because of scant facilities for in-patients in the public sector. A recent analysis (CENSIS, in press) shows that among five clusters of public services only one is judged as being efficient, and this is limited to certain regions only (Toscana, Umbria, and some areas of Veneto).

The public sector is therefore supported by the private sector, according to that type of mixed economy which allowed the Italian economic miracle, but which for psychiatry continues to raise serious doubts about any future improvement in standards.

Latitude and Affective Disorders

SIR: I am interested in the effect of latitude on the expression of the genetic trait for bipolar disorder. Inspection of a world atlas highlights the relatively few English speaking communities within the tropics. Having practiced in Mackay, Northern Queensland, for four years, I am sure that chronic mania is considerably commoner than in the temperate latitudes, e.g. London, where I previously trained and worked.

My impression is of a 'shift to mania' in people who have the genetic diathesis for bipolar illness. I see less chronic depression (although that must be a tenuous observation) and a striking increase in the severity and duration of mania. Hence, chronic mania and manic stupor are increased. I would be interested in comments on this from those in various different latitudes, especially colleagues in Hawaii, which is equivalent in latitude to Mackay but in the Northern hemisphere.

It may be helpful if I put an order of magnitude on the occurrence of chronic mania (my *ad hoc* criterion for chronic mania is a minimum duration of 6 months, but most of the patients have illnesses of at least a year's duration). I have seen a dozen cases in the first four months of this year (the catchment area I deal with has a population of approximately 100 000). Included in those dozen cases would be two of manic stupor, or at least partial stupor.

It would be interesting to know if anyone can elucidate the possible connection between this apparent increase in the incidence of mania in the tropics and the old expression, "going troppo".

Book Reviews

Editor: Sidney Crown

The Heredity of Behavior Disorders in Adults and Children. By S. G. VANDENBURG, S. M. SINGER and D. L. PAULS. New York: Plenum. 1986. Pp 301. $35.00.

Reliable psychiatric diagnoses, new mathematical models and recombinant DNA technology have followed hard upon one another in the past decade to make psychiatric genetics not only respectable, but suddenly big business. Huntington's disease and narcolepsy have been tracked down on the genome and, even as this review is written, reports are emerging of the genes for manic depressive psychosis on chromosome 11, Tourette syndrome on chromosome 18 and Alzheimer's disease on chromosome 21. No-one could dispute the need for a contemporary textbook on psychiatric genetics.

The aims of this jointly-authored book are clearly set out after a foreword by Dr Elliott Gershon: these are to review the evidence for the importance of genetic factors in mental disorders, to show how this can further our understanding of their epidemiology, and at the same time to emphasise that genetic influences do not spell immutability. The text is written consistently well. However, in Chapter 2 ('The Diagnosis of Psychopathology') a small alarm bell sounds: they are evidently not entirely comfortable with the medical model. Such ambivalence is no bad thing in the right context, but it puts the authors of a book on genetics in a curious position. Take the title, for instance: what is meant by "behaviour disorders"? It is a term the authors choose not to define, despite their preoccupation (often justified) with operational definitions throughout the text. With a single exception (epilepsy), all the disorders they consider are better known as psychiatric disorders.

Chapter 3 reviews genetic causes of mental retardation and is used to introduce concepts in cellular genetics, such as mitosis and mosaicism. Chapter 4 is potentially the most important, and deals with the methodology of psychiatric genetics. The advantages and limitations of twin, family, and adoption studies are discussed capably, as is the importance of rigorously defining phenotypes and guarding against aetiological heterogeneity. The concepts of linkage and recombination and the use of restriction fragment length polymorphisms to detect linkage are explained clearly. Multifactorial models are rightly explained at length. This comprehensive section does miss one or two basic building blocks, nonetheless. The definition of fundamental terms of measurement in population genetics is, surely, mandatory in a text like this. Their inclusion might also have served to tighten up the authors' own use of these terms, which is occasionally lax (what are "lifetime rate" and "incidence of risk"?)

The genetics of epilepsy are tackled next. Here, the authors seem to be out of their depth. We read of what "medical experts believe", and are given unabashed citations from textbooks of general neurology. Chapter 6, on schizophrenia, sees the authors back on dry land, but with legs still shaky. A workmanlike account of genetic studies leaves largely unexplored the potential significance of "schizotypical" (*sic*) personality and schizophrenia spectrum disorder. In the authors' own words: "For a thorough review of the evidence for a genetic basis for schizophrenia, see Gottesman and Shields (1982)".

However, there follow good, clearly argued chapters on alcoholism, criminality, and a variety of childhood disorders. Those concerning specific reading disabilities, stuttering, and Tourette's syndrome are particularly good, reflecting the authors' own interests. Elsewhere there are sections on affective disorders and the neuroses. Alzheimer's disease warrants two poorly-informed pages.

In summary, this book is a brave attempt to hit a fast-moving target. There are few references more recent than 1983. Joint authorship ensures a uniformly readable style, but betrays some gaps in the authors' collective expertise. Might a book like this benefit from discussion of related issues such as genetic counselling and, since the orientation is towards behaviour disorders, consideration of the genetics of some aspects of normal behaviour, such as personality? University libraries would reasonably be expected to own a copy, but interested individuals might best be advised to wait; with a growth area like genetics, it is a fairly safe bet that there will soon be more than one book to choose from.

SHÔN LEWIS, *Lecturer, Institute of Psychiatry, London*

The Nazi Doctors: A Study of Psychology of Evil. By ROBERT JAY LIFTON. London: MacMillan. 1986. Pp 561. £17.50.

Robert Lifton is justifiably renowned for the scholarly attention and ethical commitment he has given to the subject of man's confrontation with the extremes of human condition. His work on the Hiroshima survivor, the Vietnam war veteran, and the threat of massive genocide through the deployment of the nuclear bomb testify to his success. In turning to the Holocaust, and particularly to the contribution of the Nazi physician therein, Lifton has tackled, arguably, an episode unparalleled in history – the vigorous attempt to exterminate an entire people, based on racial ideology. Although we are provoked to anguish over the question of how a previously civilised state could resort to such barbarity, Lifton's chief purpose is to shed light on what motivated the Nazi physician to forgo his ethical and healing role and assume the role of killer.

Two principal themes emerge with brilliant clarity. The first is uncomfortably linked to the psychiatric profession. The eugenics movement in the early 20th century found an eager audience in Germany, and meshed neatly with Hitler's racial doctrines. It was the likes of the psychiatrist Alfred Hoche (in an influential book co-authored with the jurist Karl Binding) that provided a 'scientific' foundation upon which the Nazi regime could promulgate, as early as July 1933, a law permitting the sterilisation of the chronically mentally ill and the intellectually retarded.

'Mercy' killing of these 'lives unworthy of life' was the logical next step. Soon after the start of the war the gas chamber was installed in a number of psychiatric hospitals, and the psychiatrist came to assume the role of executioner. Over the next two years, he was to acquire an expertise and proficiency that resulted in about a quarter of a million deaths. Thus, when the 'Final Solution' was devised in 1942, the machinery of genocide was ready, and the physician was prepared for his task of selection on the ramps at Auschwitz and for the supervision of the grisly procedure in the gas chamber.

The medical profession may have unwittingly provided a scientifically plausible rationale for the decision to exterminate the Jewish 'sub-human' race, but how could physicians like Josef Mengele and Eduard Wirth (the chief doctor at Auschwitz) have allowed themselves to be recruited to the ranks of killer? Lifton offers us an explanation by resorting to the phenomenon of 'doubling': the deployment of a second 'Auschwitz' self – a complement to the previous self of ethical doctor, husband, and father. Since the two, he argues, were totally autonomous, all requirements for moral responsibility could be transferred to the Auschwitz self and in turn to the pervasive Nazi ethos with which that self was fully identified.

Lifton's propositions help to illuminate what seems to be inherently incomprehensible. If he is unable to offer a totally convincing explanation, then he is in good company; Hannah Arendt, Mary Midgley (in her excellent essay on Wickedness), Erich Fromm and others have all wrestled with the dimension of evil in man's behaviour, and only succeeded partially. Lifton's book deserves close scrutiny by psychiatrists. They will gain in at least two significant ways: by acquiring a greater understanding of the nature of human destructiveness, and by realising how vulnerable their profession is to gross unethical pursuits.

SIDNEY BLOCH, *Consultant Psychotherapist, Warneford Hospital, and Clinical Lecturer in Psychiatry, University of Oxford*

Drugs, Ageing and Society: Social and Pharmacological Perspectives. By BRUCE BURNS and CHRIS PHILLIPSON. Beckenham: Croom Helm. 1986. Pp 180. £19.95.

On opening this book, one is surprised that in a stiff-backed volume of relatively high cost, poor quality paper and typewriter setting have been used. The title is puzzling and somewhat unfortunate: it *could* imply that the authors are examining drug addiction in the elderly, rather than medication. They claim to "critically review the use and marketing" of medication used in the elderly. This aim tends to become obscured by the presentation of much data, which at times is repetitive. It is unclear for whom this is written. The authors suggest it could interest geriatricians, sociologists, psychiatrists, and pharmacists. Is it really then necessary to define dementia, postural hypotension, or beta blockers, to name but a few?

Numerous references are quoted. These range from respected authors to the *Mail on Sunday* and *Everywoman's Doctors Book of 1934*. It is difficult to take such information seriously, and this tends to detract from the important questions addressed. The chapters of special interest to psychiatrists include critical comment on the high use of psychotropic medication in the elderly. However, this is not balanced by a discussion of the high incidence of psychiatric illness in old people. Also, "unacceptable behaviour" in the elderly in elderly people's homes *does* need to be controlled – such control is by no means necessarily a "punitive" measure.

Sadly, despite the amount of sound information presented in this book few conclusions are reached, and I remain as unclear about the inter-relationships between drugs, ageing, and society as I was before reading it.

DORCAS KINGHAM, *Senior Registrar, Barrow Hospital, Bristol*

Grieving: A Handbook for Those Who Care. By RUTH BRIGHT. Missouri: MMB Music Inc. 1986. Pp 229. $19.50.

This book, written by a music therapist of 25 year's clinical experience, makes several claims, notably that (a) it is suitable for a wide readership, and (b) it provides a practical approach. The first claim is justified: practitioners and laymen can learn from this book, as can the bereaved themselves. The researcher should also find it inspiring, because (by her own admission) the author is essentially a pragmatist and many of her ideas require more formal scrutiny and testing. The rigorously-minded academic would be disappointed, therefore, if he were to expect this book to be a source of carefully-researched ideas and principles.

The second claim is also appropriate, because the author describes in some detail how she puts her ideas into practice. More specifically, for the uninitiated, there is a chapter on music therapy, and there are references to its use throughout the book. Although medicine and music have a long association, music therapy is still relatively unfamiliar to most clinicians.

It is an unpretentious book, written in clear prose. Maybe I am a Philistine, but I do not share Dr Kastenbaum's claim in the Foreword that 'musical sensitivity can be felt throughout this book in its rhythms, structure, and invitation to respond'.

The earlier chapters provide helpful descriptions of reactions to various forms of loss, including chronic disability, old age, loss of material possessions, and loss of role. There are also useful sections on the difficulties facing those who have to deal with the grieving and dying, including those individuals who are involved in the emergency services and rescue work.

In conclusion, I found this an interesting book written by an obviously sensitive and experienced practitioner whose professional philosophy includes the need to respond to individual differences among those who are grieving, and to adopt an eclectic and flexible approach to help them.

David A. Alexander, *Senior Lecturer and Acting Head of Department, Medical School, University of Aberdeen*

Modern Psychoanalysis of the Schizophrenic Patient: Theory of the Technique (2nd edition). By Hyman Spotnitz. New York: The Human Sciences Press. 1985. Pp 337. Price not stated.

This is the second edition of a book which was required reading in the course of basic training at 'Modern Psychoanalytic' Training Institutes in the United States. Before reading it I was unaware of the Modern Psychoanalysis movement, and I was interested to learn that there are eight Training Centres in the United States, and that since 1976 they have been publishing their own journal, *Modern Psychoanalysis*.

The term used for this treatment method, however, I find confusing. Patients are seen once or twice per week, and the method seems to centre around ventilation of accumulated frustrations, with a number of tactical manoeuvres available to ensure this process occurs: "Any technique employed to deal with resistance is regarded as permissible." Examples are given, such as telling a patient who does not wish to talk to "Keep quiet", with the intention that a contrary-wise patient will then talk. This is clearly not psychoanalysis, and I was unhappy with Spotnitz's statement that his treatment approach is "basically Freud's theory and Freud's method of therapy." Also, he justifies the use of the term 'modern' with too many quotations from the early days of psychoanalysis, as if there have not been many developments in the past one hundred years.

The important issue of diagnosis was left unclear in my mind. Although a short section is devoted to reviewing diagnostic criteria in general, I could find no definite statement about the diagnostic criteria for the patients treated by this method. Clinical examples are mainly to be found in the last chapter of the book, where various therapeutic interventions and strategies are described. The patients came across to me as more integrated individuals than the schizophrenic patients I am accustomed to, and I wondered if this reflected a diagnostic difference. The book in general made more sense to me as a psychotherapeutic approach to treating patients with personality disorders and chronic neuroses.

On the more positive side, there is a chapter on the development of the therapeutic alliance which I found useful reading, and the reference list is comprehensive. There would also be little disagreement with the emphasis given to the therapist's capacity to cope with treating patients with narcissistic disorders.

On the whole, in spite of the exciting title, I failed to find this a particularly stimulating book.

Tom Murphy, *Consultant Psychiatrist, Royal Dundee Liff Hospital, Scotland*

Neuropsychological Rehabilitation. Edited by Manfred J. Meier, Arthur L. Benton and Leonard Diller. London: Churchill Livingstone. 1987. Pp 475. £45.00.

It is only in the past 10–15 years that neuropsychologists have become interested in rehabilitating the patients they have so assiduously studied to elucidate the relationships between brain and behaviour. This book provides a comprehensive account of these endeavours and what they have achieved so far. In general, the results are disappointing. The major emphasis is on careful and accurate assessment of disabilities, and the first part of the book is devoted to this topic. However, many of the chapters in the second part (representative research and application) are also largely concerned with assessment, with only a nod towards rehabilitation at the end. Many still believe that given a sufficiently careful assessment, the steps needed for rehabilitation are self-evident.

In my opinion the major contributions that neuropsychologists can make to the study of rehabilitation are firstly, to provide theories of the restoration of function, and secondly, to design experiments to show which types of rehabilitation are successful. It appears that, as yet, few attempts have been made to do either of these. As one contributor puts it "The description of the procedure is anecdotal and no data are presented". With regard to the lack of controlled trials, the all-too-frequent false moral is put forward that it is unethical to withhold treatment. This problem must be balanced by the lack of ethics in pinning hopes on procedures with no proven value.

The book is somewhat carelessly edited, in that there is much unassimilated overlap between different contributors. Also, some have reviewed their topic in detail while others have restricted themselves to their own specific interests. Posner and Rafal describe an interesting theory of attention, but are not yet able to come up with specific suggestions for rehabilitation. O'Conner and Cermak provide a useful account of the rehabilitation of memory disorders, and Anna Basso does the same for disorders of language. The last part of the book summarises what is actually being done in rehabilitation centres throughout the western world. Given all this activity I am sure there will be great advances in the neuropsychology of rehabilitation over the next ten years. This book has perhaps appeared prematurely.

CHRIS FRITH, *MRC Senior Scientist, Clinical Research Centre, Harro*

The Psychology of Child Firesetting: Detection and Intervention. By JESSICA GAYNOR and CHRIS HATCHER. New York: Brunner/Mazel. 1987. Pp 220. $25.00.

Arson is one of the commoner serious and dangerous crimes in this country and the USA, where, surprisingly, a third of all fire-setting is by children. Certainly the incidence in the UK of fire, in particular school fires, set by children and teenagers has drastically increased since my book *Fire Raisers* was published ten years ago. It is, nevertheless, a common observation that virtually all children play with matches. How then does this relate to serious fire crime? Any study on the subject is clearly of great importance. The current book by two psychologists is of particular interest because it reports a long programme of work in co-operation with the San Francisco Fire Department.

There are two main sections: detection and intervention. The former is based on a predictive model suggesting that 'fire interest' is channelled, because of various psychosocial determinants, into the 'fire safe' or the 'fire risk' categories. There are many useful tabulations provided in this section of the psychological and physical characteristics of fire-setters, but it is a pity that more case material is not provided.

The great variety of intervention processes, psychotherapeutic and behavioural, that can be employed are described, both for the individual and the family, as well as methods of patient selection. Of considerable interest are community intervention methods with schoolchildren in different age groups. The approaches vary in different parts of the United States. In one the cost-effectiveness was assessed, but on the whole follow-up information is limited. The final chapter suggests the appropriate roles of various agencies and professionals involved, including the physician. Much useful help in a difficult field is provided by this reasonably priced book, but it is clear that more remains to be done, particularly in the evaluation of intervention methods.

D. F. SCOTT, *Consultant Neurophysiologist, The London Hospital*

The Therapy of Pain (2nd ed.). Edited by MARK SWERDLOW. Lancaster: MTP Press. 1986. Pp 271. £32.95.

This is a second edition of a valuable textbook on pain management. It contains an update on the neurophysiological aspects of pain (Cervero) and there is a balanced and informative chapter on the role of the psychiatrist in the management of chronic pain (Pilowsky). Lipton and Swerdlow provide helpful and brief descriptions on the management of a pain relief centre and assessments of the pain patient. The chapter on pharmacological management of pain (Williams) provides practical advice for those interested in pain management. Unfortunately, however, there is an uncritical acceptance of treatments such as transcutaneous nerve stimulation, trigger point therapy, and biofeedback, none of which have been shown to be more valuable than the placebo in controlled studies. The chapter on non-invasive methods in pain relief accepts the value of these therapies without question (Mehta). The chapters on nerve blocking and neurosurgery for pain relief are well illustrated and helpful (Charlton and Hitchcock). Low backpain has been singled out for an independent chapter, and Porter's contribution provides sensible advice. The final chapter on oncological management is excellent (Saunders).

The quality of the book is good. I think it is a useful book for students and practitioners alike, but I would like to see more critical evaluation of therapies such as trigger point therapy, as there is a danger that they gain respectability without having been adequately tested.

CHARLOTTE FEINMANN, *Consultant Psychiatrist, Eastman Dental Hospital and Senior Lecturer, Middlesex Hospital and University College Hospital*

The Psychopharmacology and Treatment of Schizophrenia. Edited by P. B. BRADLEY and S. R. HIRSCH. Oxford: Oxford University Press. 1986. Pp 457. £37.50.

Although some reference is made in this book to the social methods of management of schizophrenia the emphasis of the volume as a whole is very much towards drug treatment. One might imagine that a book of this size devoted to this topic would be inclined to be repetitious and would be covering a good deal of well-ploughed ground. The editors are to be congratulated on the fact that this is not the case. They have incorporated some unusual chapters, bringing together topics which are not often discussed, and the chapters which deal with well-known areas of work generally do so in a careful and informative way.

The opening chapter, on peripheral biochemistry, elegantly draws together a number of areas of work which are relatively unfashionable among clinicians and other scientists but some of which tend to come to the attention of sufferers and their relatives. Clinicians who would like a convenient source of references in order that they may present concerned individuals with facts regarding zinc and magnesium metabolism, prostaglandins, and gluten sensitivity in relation to schizophrenia need to look no further. The chapter on the pharmacology of antipsychotic drugs is accurate, informative, and well referenced, as indeed are those on animal models, applied clinical pharmacology, and neurotransmitter hypotheses of schizophrenia. The case for the use of animal models in psychiatric disorders is made so persuasively that it must convince all but the most cynical of clinicians.

These chapters are followed by a series of competent and useful essays on clinical issues relating to the study of schizophrenia; these include diagnosis, the influence of social factors, and rating scales which may be used in schizophrenia. The chapter on the difficult issue of essential elements in the design of clinical trials is particularly well done. The thoughtful and well organised chapter on the evaluation of social functioning covers areas which are not often addressed in this careful style. The long chapters on the clinical treatment of schizophrenia and untoward effects of antipsychotic drugs cover the issues clearly and comprehensively, and the section on extrapyramidal movement disorders produced by antipsychotic drugs is very good indeed. In spite of the fact that this book concerns areas of work with which I am very familiar it was interesting and informative and I enjoyed it. It is a well-written account of the current state of knowledge of the psychopharmacology and drug treatment of schizophrenia and will be useful to trainees in psychiatry and to established clinicians.

EVE C. JOHNSTONE, *Member of the Scientific Staff and Honorary Consultant Psychiatrist, Northwick Park Hospital, Middlesex*

Can Schizophrenia be Localised in the Brain? Edited by NANCY ANDREASEN. Cambridge: Cambridge University Press. 1986. Pp 87. £15.00.

This small volume contains the papers presented at a symposium at the American Psychiatric Association Annual Meeting. In such symposia it is appropriate to make the best of one's data and to present one's case with force and conviction. The case is after all open to argument from the floor. The papers presented here must have been very successful in that situation, and Andreasen in particular develops her argument with considerable finesse.

As a written text, however, these papers have shortcomings. Most of them have been written to make conflicting cases in a way that could provoke discussion, and I am sure the authors would not claim that they have attempted a balanced or complete review of the relevant literature. This is a style which promotes lively controversy at a meeting and which may be appropriate enough in a paper published in a journal with an active correspondence column, but it is less suitable in book form. There is no opportunity for the more argumentative reader to ask how the authors take account of the work of X, Y, and Z, or in what way the data in some of the papers cited really support the case that is made.

The last paper, by A. M. and M. A. Reveley, differs from the others. It is written in a considered and understated style which most readers will find more familiar and certainly less abrasive. The fact that the provocative quality of the other papers raises so many questions in the reader's mind may, however, be a virtue in itself. This book may raise the interest of psychiatric trainees, but it will not give them a clear view of the current state of knowledge in the field.

EVE C. JOHNSTONE, *Member of the Scientific Staff and Honorary Consultant Psychiatrist, Northwick Park Hospital, Middlesex*

Expressed Emotion in Families. By JULLIAN LEFF and CHRISTINE VAUGHN. New York: Guilford Press. 1985. Pp 241. £19.95.

The scientific approach to the study of environmental influences on the course of mental disorders has seldom been applied with the rigour expounded in Leff and Vaughan's book on 'expressed emotion'. To date more than 10 published studies have replicated the finding that the quality of the social environment in which a person lives is the best single predictor of the short-term course of schizophrenia. George Brown's remarkable first person account of the development of the 'expressed emotion' concept from 1956 to the early 1970s provides a fascinating commentary on the manner in which an intuitive experience of sensing a tense household atmosphere was eventually quantified into a highly reliable measure. The surprise and scepticism he felt on finding that this factor proved such a robust prognostic indicator has been experienced by many since.

Brown's work has been refined in the past decade. Detailed accounts of these refinements are described in the remainder of the volume. The landmark 1976 study, the London and Californian replications, and early family intervention studies are included. Although much of this material has been published in scientific journals, this book provides many additional details that will undoubtedly stimulate at least another decade of 'expressed emotion' studies.

The significance of this body of work is such that this book should be essential reading for every mental health professional and student of the social sciences.

NOTICE TO CONTRIBUTORS

1. *The British Journal of Psychiatry* is published monthly under the auspices of the Royal College of Psychiatrists. The *Journal* publishes original work in all fields of psychiatry. Communications on general editorial matters, including manuscripts for publication, printed matter, and books for review, should be sent to *The Editor, The British Journal of Psychiatry, 17 Belgrave Square, London SW1X 8PG.*

2. Contributions are accepted for publication on the condition that their substance has not been published or submitted for publication elsewhere. The *Journal* does not hold itself responsible for statements made by contributors. Unless so stated, material in the *Journal* does not necessarily reflect the views of the Editor or the Royal College of Psychiatrists.

3. Published articles become the property of the *Journal* and can be published elsewhere, in full or in part, only with the Editor's written permission.

4. Manuscripts accepted for publication are subject to copy-editing, and to editorial changes required for conformity with *Journal* style.

5. We regret that papers unsuitable for publication will not be returned.

6. **General advice to authors** In the assessment of manuscripts submitted to the *Journal*, great importance is attached to clarity and brevity of expression. Authors should read *General Notes on the Preparation of Scientific Papers* (3rd ed. 1974, £0.45, from The Royal Society) and/or Judith Butcher's *Typescripts, Proofs and Indexes* (1980, Cambridge University Press, £2.95). Spelling should follow the *Concise Oxford Dictionary*.

The standard of statistical work in papers submitted for publication has proved to be very variable. Authors using any statistical methods at all are strongly advised to study the paper 'Statistical guidelines for contributors to medical journals' (D. G. Altman *et al*, *British Medical Journal*, 7 May 1983, **286**, 1489–1493) at the earliest possible stage in preparing their work for publication.

7. **Manuscripts** Two high-quality copies should be submitted and the author should retain a copy. Articles must be typed on one side of the paper only, **double spaced with wide margins**, and all the pages must be numbered sequentially, starting with the title page.

a. The **title** should be brief and to the point. If necessary, a sub-title may be used to amplify the main title. The names of the authors should appear on the title-page, and **their names, degrees, affiliations and full addresses at the end of the paper.**

b. A **summary** should be given at the *beginning* of the article. It should be brief and factual and not normally more than 150 words.

c. **References** should be listed **alphabetically** at the end of the paper, **the titles of journals being given in full.** Authors should follow *Journal* style for the reference list and study the examples given below. Titles of books and journals are printed in italic and should therefore be underlined on the typescript. Reference lists not in *Journal* style will be returned to the author for correction.

Authors should check that the text references and the reference list are in complete agreement as regards dates and spelling of names. The text reference should be in the form '(Smith, 1971)' or 'Smith (1971) showed that . . . '

DURKHEIM, E. (1897) Le Suicide. Paris. Translated (1952) as Suicide: A Study in Sociology, by J. A. Spaulding & C. Simpson. London: Routledge & Kegan Paul.

KENDELL, R. E. (1974) The stability of psychiatric diagnoses. British Journal of Psychiatry, **124**, 352–358.

RUTTER, M., TIZARD, J. & WHITMORE, K. (1970) Education, Health and Behaviour. London: Longman.

SCOTT, P. D. (1974) Definition, classification, prognosis and treatment. In Pathology and Treatment of Sexual Deviation (ed. I. Rosen) Oxford: Oxford University Press.

'Personal Communications' need written authorisation.

d. **Symbols and abbreviations** Follow *Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors* (3rd ed. 1977), £2.00, available from the Publications Office of the Royal Society of Medicine. Terms or abbreviations which might not be understood by the average reader should be explained at first occurrence.

e. **Tables and Figures** Each table should be on a separate sheet, with an adequate heading; table and heading should be self-explanatory without reference to the text. The desired position of the table relative to the text should be indicated in the left margin.

Figures should be individual glossy photographs, or other camera-ready prints, *not* photocopies, clearly numbered and captioned below. Avoid cluttering figures with explanatory text which is better incorporated succinctly in the caption. A figure intended to occupy a single column should be drawn (or photographed) 80–110 mm wide to allow for a 2/3 reduction; a figure requiring the whole width of the page should be 180–210 mm wide. Lettering (film-set or stencil) should be 12pt sans (initial capital for the first word only) to give 8pt on the printed page. Labels on graphs should read parallel to the axes. Units must be clearly indicated and should be in brackets (*note*—'litre' should be spelled out in full unless modified to ml, dl, etc.).

f. **Photographs** Prints must be taken directly from the original b/w negative (not, for example, from a colour slide or a printed page) and should be glossy and sharply focussed. Labels, arrows, etc. should be shown on a duplicate print or overlay. Do not write anything on photographic prints, and do not use staples or paper-clips on them. These procedures apart, all the comments on figures and tables apply equally to photographs.

8. **Proofs** A proof will be sent to the senior author of an article. Reprints, which are prepared at the same time as the *Journal*, should be ordered when the proof is returned to the Editor.

9. **Letters to the Editor** Letters should not exceed two double-spaced typed pages. They will be edited for clarity and conformity with *Journal* style and may be shortened. There should be no more than five references; tables and figures cannot be used.

RESIDENTIAL COURSE ON RESEARCH METHODS AND STATISTICS

UNIVERSITY OF BIRMINGHAM DEPARTMENTS OF PSYCHIATRY AND STATISTICS

Dates: Monday 25th to Friday 29th January 1988 (5 days and 4 evenings)

Venue: Lucas Institute, Edgbaston, Birmingham.

There will be:

(1) lectures on research methods including sampling, planning of research, measurement, epidemiology, genetics and clinical observation, ethics and publishing given by Professor Brockington, Dr Sashidharan, Dr Dean and Dr Mackintosh.

(2) lectures on research design, statistics and computing given by Professor Copas and Dr Waterhouse.

(3) statistical exercises each evening.

(4) the discussion of research protocols written by participants in small groups at a final plenary meeting.

Cost £250 (resident) or £150 (non resident)

Enquiries to Dr John Mackintosh, Department of Psychiatry, Clinical Research Block, Queen Elizabeth Hospital, Birmingham B15.

The Retreat, York

for Psychiatric Illnesses

Founded in 1792 by the Quaker, William Tuke, who established the tradition of concern for patients as individuals The Retreat is a 200-bedded private registered nursing home surrounded by extensive grounds on the outskirts of the historic City of York. It is easily reached by rail and motorways.

Care and treatment is offered for all types of psychiatric illness on the short or long term in a sympathetic and friendly atmosphere. Patients suffering from neuroses, psychoses, alcoholism and dementia are treated by the full-time consultant psychiatrists in surroundings suitable for their individual needs. Outpatient facilities are available by appointment with the consultant medical staff.

The Nursing Home is a registered charity and is able to offer inclusive care in shared accommodation from £32.00 per day or in single rooms at slightly increased charge. The Nursing Home is recognised by the main private patient schemes.

For further details apply to The Medical Director, The Retreat, York YO1 5BN (Telephone 0904 412551).

Eating Characteristics and Temperament

General Measures and Interrelationships

1987. 21 tables. Approx. 150 pages. Hard cover DM 75,–.
ISBN 3-540-96510-6

Eating Characteristics and Temperament: General Measures and Interrelationships provides a comprehensive description of the various ways people eat, and how these individual eating styles relate to personality. Dr. Mehrabian introduces a new approach to the study of eating and presents innovative measures of eating and personal treatment. Based on large samples from normal populations, the research calls attention to the complex interrelationship between aspects of the personality and eating. General measures of temperament provide a basis for comparing the results of this important effort with past research on arousal, temperament, and emotions.

B. J. Guinagh, University of Florida, Gainesville, FL

Catharsis and Cognition in Psychotherapy

1987. Approx. 135 pages. Soft cover DM 49,50.
ISBN 3-540-96530-0

This book presents, in a highly readable form, the essentials of psychotherapy and the role of thoughts and feelings in the therapeutic process. The basic premise is that psychotherapists help individuals with emotional problems through the use of techniques that build on the natural processes of catharsis and cognition. Cathartic therapists encourage the expression of emotion while cognitive therapists encourage the examination of thought processes. **Catharsis and Cognition in Psychotherapy** describes the research and theory which has nurtured the historically important relationship between these two major factors.

N. Peseschkian, Wiesbaden

Positive Psychotherapy

Theory and Practice of a New Method

Translated from the German by R. Walker
Illustrations by R. Henkel

1987. XIX, 443 pages. Soft cover DM 48,–. ISBN 3-540-15794-8

The author's model of **Positive Psychotherapy** is a synthesis of psychodynamics and behavior therapy that focuses on the positive aspects of conflicts and sufferings. He offers transcultural perspectives in the form of proverbs, myths and fables in which the patient may recognize himself in allergorical terms and thus be able to establish a new form of selfconfidence and security.
Positive Psychotherapy introduces the methods and therapy models of differentiation analytical psychotherapy. The discussion lays the theoretical foundation of Peseschkian's approach: that illness can be a reflection of conflict within the individual or between him and his surroundings.

Social Processes in Clinical and Counseling Psychology

1987. Approx. 1 figures, 3 tables. Approx. 392 pages.
Hard cover DM 68,–. ISBN 3-540-96533-5

This book applies social psychological theory and research to enhance and offer new perspectives on clinical and counseling psychology. Numerous experts present and review current research in the field with a strong applied and practical emphasis. Each chapter succeeds in making a useful suggestion about working with clients in psychotherapy and counseling. Researchers in social psychology will come away with a renewed appreciation for the practical and applied potential of their work; clinical and counseling psychologists should come away with some new perspectives that may change the way they interact with their clients.

H. Schepank, Mannheim

Epidemiology of Psychogenic Disorders

The Mannheim Study
Results of a Field Survey in the Federal Republic of Germany

In cooperation with numerous experts
Translated from the German by R. Mills

1987. 9 figures, 36 tables. Approx. 190 pages. Soft cover DM 58,–.
ISBN 3-540-18027-3

This book presents for the first time the results of a ten-year research project on the epidemiology of psychogenic disorders (psychoneuroses, character neuroses and psychosomatic disorders). The study concentrates on the age group relevant for psychotherapeutic care: 25–50 year olds living in urban communities. The results show that 26% of the population suffers from these symptoms and would be cases for clinical treatment.

Announcing the new DSM III R

NEW FEATURES

- Diagnostic criteria revised throughout to be clearer and more clinically useful
- Greatly expanded section on substance abuse
- New classification and criteria for the sleep disorders
- The Multi-Axial System has been revised
- Revised decision trees
- Entire text redesigned for easier reference:
  - criteria clearly set off with bold headings
  - running heads at top of page
  - page numbers triple referenced in the classification, table of contents and index
  - individual criteria in alphabetical order within major classifications wherever possible

Diagnostic and Statistical Manual of Mental Disorders

Third Edition Revised

AMERICAN PSYCHIATRIC ASSOCIATION

The entire text of the highly successful DSM III has been revised to take account of the latest data available for the consideration of associated features, the course, complications, prevalence, differential diagnosis and other factors that influence the diagnosis of mental disorders. In particular the diagnostic criteria have been revised, there is a new classification and criteria for sleep disorders, and a greatly expanded section on substance abuse. The book has been redesigned to make it easier to use, with many useful features incorporated.

TEACHING EVENTS PROGRAMME

AUTUMN 1987–EASTER 1988

The Institute of Family Therapy's programme of teaching events for Autumn 1987–Easter 1988 is now available. This covers a range of workshops and short courses which will take place at the Institute during this time.

A further brochure, covering the period Easter–Autumn 1988, will be available from the Institute in the Spring.

Further details available (with SAE) from:
The Training Secretary, Institute of Family Therapy, 43 New Cavendish Street, London W1M 7RG.

U.M.D.S. Guy's and St. Thomas's Hospitals

MRCPsych Part I Course

This course has been substantially revised to prepare candidates for the new Part I of the Membership Examination. It recognises the major shift of emphasis between the Part I and Part II Examination, and is designed to prepare candidates for an examination in basic clinical psychiatry together with relevant aspects of basic science.

The course will start in October 1987 and will run for three terms, each term consisting of ten half-day sessions (on Monday afternoons) and one whole study day.

There will be extensive use of video techniques in teaching methods of clinical assessment, and each candidate will be expected to prepare, in his/her own time, videotapes of interviews they have conducted with patients.

Fee £300 payable on registration. Candidates should apply to the Postgraduate Secretary, Division of Psychiatry, U.M.D.S. Guy's Hospital, London, SE1 9RT.
(Tel: 01-407 7600 Ext. 3109)

PSYCHIATRIST

The Department of Mental Hygiene of The Johns Hopkins University School of Hygiene and Public Health is engaged in an international search for a psychiatrist committed to the public health perspective and interested in research on the mental health service system. The Department provides a multi-disciplinary environment, centered on epidemiologic approaches to psychopathology. We have close ties to the Department of Health Policy and Management, including a five-year NIMH award to establish a Center for the Study of Financing and Organization of Services to the Severely Mentally Ill. The Department has also been designated to design the Management Information System for the City of Baltimore's current reorganization of its mental health service system under the auspices of a five year grant from the Robert Wood Johnson Foundation. We expect the candidate, in collaboration with others in the Department and the University, to use these and other resource bases to design, obtain funds for, and conduct quantitative modelling, evaluations and preventive trials which will improve the mental health service system. Thus, the candidate selected will be a central part of the research team that is expected to have a major influence on the necessary reshaping of the mental health service system in the United States.

This appointment can be made at whatever level is justified by the record of the candidate. A joint appointment in the Department of Psychiatry is anticipated.

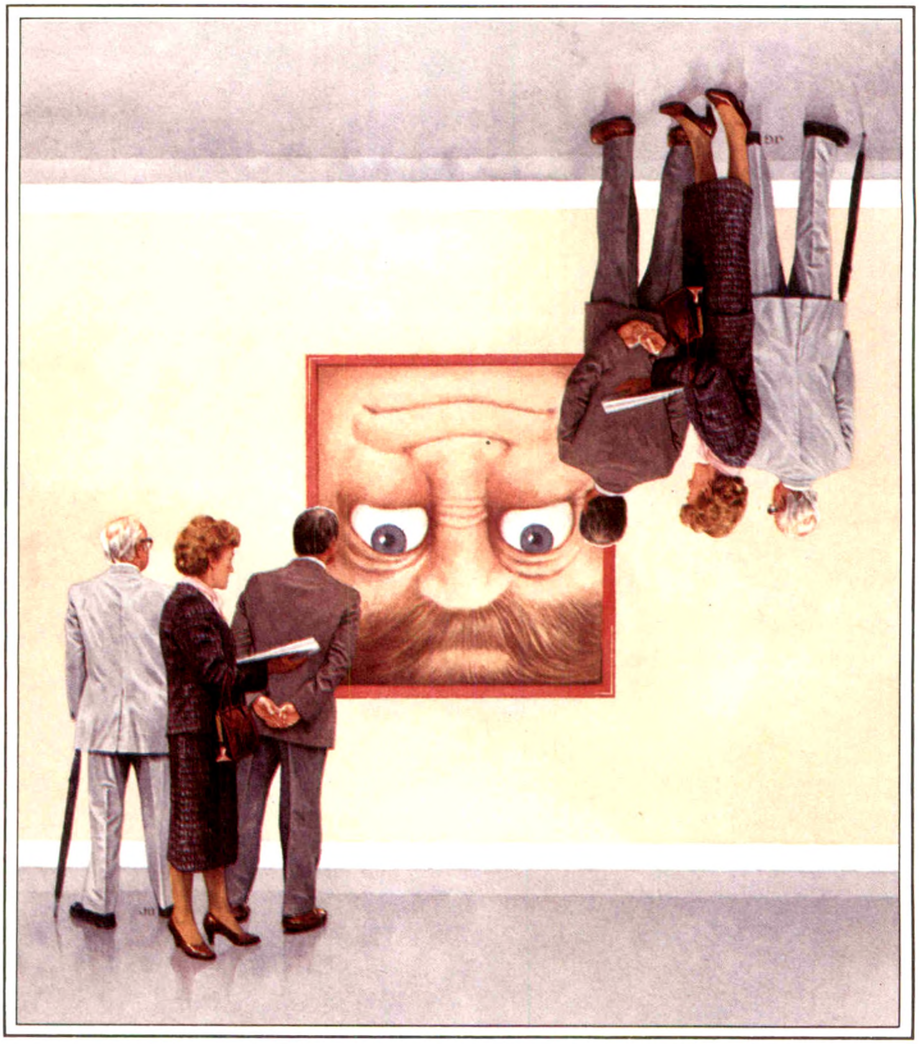
Modecate Abbreviated Prescribing Information. Indications: Treatment of psychotic disorders. **Dosage – Modecate injection 25mg/ml.** Most patients are successfully maintained within the dosage range 12.5mg (0.5ml) every five weeks to 100mg (4ml) every two weeks. For full dosage information see Data Sheet. **Modecate concentrate injection 100mg/ml.** Adult patients found to require larger volumes of Modecate 25mg/ml may be transferred directly to the equivalent dose of Modecate concentrate on the basis that 1ml Modecate concentrate is equivalent to 4ml Modecate. **Contra-indications.** Patients with marked cerebral atherosclerosis, phaeochromocytoma, renal or liver failure, or severe cardiac insufficiency. **Precautions.** Care should be taken in patients, particularly the elderly, who exhibit marked extrapyramidal reactions to oral phenothiazines. **Side effects.** Mainly extrapyramidal reactions. Drowsiness, lethargy, dryness of the mouth and mild hypotension may occur. **Product Licence No's and Prices. Modecate injection 25mg/ml.** PL 0034/5046. 10 x 1ml ampoule £25.20 **Modecate concentrate injection 100mg/ml.** PL 0034/0189. 10 x 0.5ml ampoule £49.99 5 x 1.0ml ampoule £48.86. Modecate is a Trade Mark of E. R. Squibb & Sons Ltd. Further information available from: Technical Services Department, E. R. Squibb & Sons Ltd., 141-149 Staines Road, Hounslow, Middlesex TW3 3JA. Tel: 01-572 7422.



TRIED AND TRUSTED

19 years ago, E. R. Squibb & Sons helped lead a revolution in the community based treatment of schizophrenia when they introduced the depot neuroleptic concept.

Since then worldwide clinical experience has confirmed the efficacy and safety of Modecate in over 800,000 patients.

Modecate is now regarded by many psychiatrists as the standard depot neuroleptic.

MODECATE®

25 mg/ml

100 mg/ml

FLUPHENAZINE DECANOATE

Modecate is available in two strengths, allowing a wide dosage range with convenient injection volumes.

Most patients can be controlled with an injection at intervals of 3 weeks or more.[1]

Modecate is less expensive than other depot neuroleptics when comparing equipotent doses.

Annotation

Psychotherapy Today

Further Consideration of the Essence of Psychotherapy*

STANLEY E. GREBEN

Despite swings between over-valuation and rejection of psychotherapy on the part of some psychiatrists, there remains a valid and necessary place for psychotherapy in psychiatry. The essential elements of that place are described.

Six years ago, I endeavoured to abstract what it is that matters and is effective in the practice of psychotherapy (Greben, 1981). There have since been important shifts in the attitudes of psychiatrists toward the value or lack thereof of psychotherapy. At the same time, many other professionals have become active in psychotherapeutic work. Members of the public, needing help for symptoms that discomfit them and diminish the quality of their lives, are often hard pressed to find useful help, both within and without medical facilities.

My awareness of this circumstance has been heightened by responses of both professional and lay people to views expressed in my book, *Love's Labor* (Greben, 1984). Patients and family members, some of whom are psychiatrists, expressed concern, dismay, even outrage, at ways in which they or others had been dealt with in psychotherapy. We need to address these concerns, if we intend psychotherapy to be a respectable component of our therapeutic armoury.

I intend to set out my current view of what should be the place and use of psychotherapy, from the vantage point of one who is a medical specialist in psychiatry and also a psychoanalyst, working in a teaching general hospital. I will also deal with issues that are important to other professionals in the health field, as well as to the consumers of our services. I hope to bring perspective to an area which is of great importance, not only to those of us who work in it, but to Western society in general.

In examining factors which I feel to be effective in bringing about change through psychotherapy (Greben, 1977), I began with the proposition that psychotherapy *does* lead to changes in patients, and that this has been amply demonstrated by numerous studies (Smith *et al*, 1980; Karasu, 1982), as well as by the observations of experienced clinicians. The challenge was to then demonstrate what are the reasons for the improvements that occur. As I set out in that instance with the relatively optimistic point of view that psychotherapy does work, I set out in this instance with the relatively optimistic view that much excellent psychotherapeutic work is taking place. At the same time, a considerable amount of work has been done that is not acceptable, and has not met justified expectations of those who have sought help.

Influences of society upon psychotherapy

As medical scientists, we prefer to think of the scientific part of our work as freestanding from popular attitudes in society, but of course it is not. Even 'hard' basic sciences are subject to the pull of current public attitudes. With psychotherapy, a number of external influences have played an important part in the directions which both our theory and practice have taken.

Freud developed psychoanalysis in Vienna at the turn of the century. Despite a milieu of relative psychological repression and denial, in a stratified society where surface and depth were so at odds, he was able to be candid and revealing about his feelings and findings. That candour was essential to the beginnings of a profession devoted to the uncovering and revelation of realistic truth. Freud's discoveries were of course consistent with the content of classical writings of centuries before: the authors of the Scriptures, Roman and Greek philosophers, Shakespeare, and Dickens clearly understood these principles. As Freud indicated, he became famous revealing "what every nursemaid knows".

The Second World War displaced European psychoanalysts, principally to England and the United States, and that which had been of mild influence came to be of much greater influence. They became, especially if their direct lineage could be drawn to Freud, a kind of guru. In those years, many people in Western society were uncertain about themselves, and about the form and direction which it was best for life to take. Scientists seemed to have important answers to the dilemmas that faced most people. Fear, ennui and insecurity abounded. The American child psychiatrist, Leo Kanner, alarmed by this phenomenon, wrote a book entitled *In Defence of Mothers* (Kanner, 1962).

---

*Based on a lecture given to the Department of Psychiatry, University of Western Ontario, October 1986.

After the war, psychoanalysis dominated psychiatry, and also had a powerful general influence upon Western society. Much has since changed. Too much was expected of psychoanalysis by its practitioners, consumers and general adherents, and so disillusionment ensued. Many reasoned that helping people live more fruitfully and happily did not necessarily require years of formal training and personal psychoanalytic treatment. Anti-traditionalism thrived in all areas, and psychotherapy was no exception. Beginning among other places in Big Sur, California, everything old was rejected and everything new was attempted. Touching, holding, in addition to talking, was tried. All manner of theories were expounded and, for a time, cherished.

As we emerge from all that to a time when traditional and conservative values are coming once again to the fore, the work of Freud, Jung, Winnicott, Klein, Greenson and many others has not disappeared. Still, the influence of freer psychotherapy which demands more participation of the therapist has continued, and is likely to have a lasting effect upon the development of a general psychotherapy.

Another important and wholesome recent influence upon psychotherapy has been the view that people have a right to receive something evident and helpful when they spend time, money and energy seeking help. Numerous psychoanalysts took, in past years, the view: "I don't try to help people, I analyse them. Analysis is an art." Many people today do not accept that view. Correctly, professional practitioners are now being held to more account, both by those who provide financial support and by those who are the objects of that work.

Another societal influence upon the practice of psychotherapy arises out of the growing intention of people to live in more natural ways, avoiding the noxious effects of poisons and of disuse. Such 'holistic' approaches presume that that which is closer to nature and the experiences of our ancestors is most likely to suit us well, and do us the least harm. For all psychotherapists, an understanding of Oedipus and Psyche is insufficient. For the physician psychotherapist this carries particular implications, for he is expected to understand, not simply to dismiss, the significance for health of nutrition, exercise, meditation, hypnosis, yoga, and other special practices which have withstood, presumably for good reasons, the practical test of time. He must, for example, know the work of Benson (1974), so that he can assess his patient's search for techniques that will induce the relaxation response. All physicians must know the accumulated evidence of the benefit of a diet which is low in fat, simple sugars and salt, and high in complex carbohydrate and fibre. They must be equally cognisant of the multiple benefits of avoiding underuse of the body, recognising that the release of endorphins and epinephrine into the bloodstream has a profound effect upon mood and mentation and, aware of the dangers of substance abuse for the relief of the effects of stress and unhappiness, should encourage patients in the less dangerous habituation of regular and sustained athletic activities. Similarly, the psychotherapist who ignores the place of humour in becoming and continuing to feel well (Cousins, 1979) will be a very limited psychotherapist indeed. In short, we have ample proof that insular psychotherapies are inadequate and cannot succeed.

Another attitude has been growing in strength and popularity that must be paid heed to by psychiatrists. Considerable dissatisfaction is being expressed about the ways in which health care is provided. In part this arises because of a general deterioration in the quality of caring for others in everyday life. In part it relates to the cost of physicians' services, both physical and psychological. Complaints are now openly heard that physicians are more technicians and less care-givers. More demand is being made for humane, individual care of patients. This dissatisfaction, on the part of both physicians and patients, demands redress.

This trend has considerable significance for psychotherapists. Ten and twenty years ago I knew of patients in intensive psychotherapy or psychoanalysis whose therapists said literally nothing for months on end of several-times-weekly treatment. Today, when patients have come to feel more deserving of humane, active treatment, such neglect, even when benign, is less likely to be tolerated. This is a very good thing. The days when psychotherapists were gratefully attended and paid for just being present in the room are passing or passed. We are being expected, as are all professionals who are paid for their time and services, to produce something that will be useful and valuable to the patient.

One encouraging manifestation of these changed attitudes has been the establishment of a new international journal entitled *Humane Medicine*. Its stated purpose is: ". . . to provide a vehicle for communication among all those who have something to share about ministry to the whole person – to body, mind and spirit" (Oreopoulos, 1985). The provision of such a forum, bringing together the concerns of both health care professionals and their clients or patients, bespeaks a new attitude that has profound implications for the practice of psychotherapy. That attitude expects people to be treated well and respectfully, and to be given something valuable for the time, energy and money which they invest in the pursuit of health and comfort. A main goal of psychotherapy is the growth, maturation and psychological development of the patient, and these can take place only under the conditions that are currently being expected of us (Marmor, 1977).

Overall, those influences in society which currently pull us more into the mainstream, are likely to improve both our relations with our patients and the ways and degree to which we are able to be of help to them.

Influences of other professions upon psychotherapy in psychiatry

In recent years there have also been important relevant changes in the attitudes and activities of our fellow professionals, and in our attitudes toward them. Some psychiatrists adhere to the view that psychotherapy is a medical act only, and can properly be undertaken only by medical personnel. This is not a view that can be logically supported, since the largest part of what is done, most of the time, in psychotherapy is psychological, and has not to do with physical or medical matters. Others hold the opposite view: that psychotherapy is not a medical act, and that medical training is irrelevant to its performance. This view is also illogical, for much that presents as psychological disturbance originates in medical disease, and much that is treated solely by psychological means cries out for biochemical or other medical therapy.

A reasonable view would be that there is a place for psychotherapy to be practised by both medical and non-medical professionals, and that the advantages and limitations of the training and experience of each specific profession need to be recognised. From the vantage point of psychiatry, psychotherapy must continue to be taught, studied, and practised as an indigenous part of psychiatry (Katz, 1986). At the same time, it is appropriate that we find ways of co-operating with members of other professions, not just competing, in this area of our work.

In the history of psychotherapy, both as a science and as an art, a major role has been played by both physicians and non-medical workers, most obviously within psychoanalysis, but also in the field of psychotherapy research. It is healthy for psychotherapy that workers come to it from several professions, for in that way the effect of blind spots that exist in each profession is reduced. The territory of psychotherapy is large, and research by both physicians and others has produced fruitful results.

Influence of attitudes of psychiatrists and other medical psychotherapists upon psychotherapy

In recent years, some medical practitioners, including psychiatrists, have been prepared to eliminate psychotherapy as an indigenous part of psychiatry, and to delegate its practice to others. This tendency is against the entire history of the profession of medicine and of the specialty of psychiatry. There are training programmes for residents in psychiatry in which psychotherapy supervision for residents has been given over to a psychologist. There are hospitals in which suitability of a patient for psychotherapy is determined not by a psychiatrist, but again by a psychologist. This is not the major trend in psychiatry, but it should be strongly discouraged. For psychiatrists to relinquish the study, practice and teaching of psychotherapy is to be absolutely avoided, since doing so would lead them to be not medical psychologists, to use an old term, but behavioural physicians, and would justify the apprehensions, fears and even expectations of those who see medical practitioners as becoming more and more technicians, and less and less clinicians.

Another attitude which has hindered the development of the most useful general medical psychotherapy has arisen out of the use of our most important medical tool, the scientific method. This tool will always be the most reliable means of drawing trustworthy conclusions within any arena. Still, out of excessive respect for that method, we have tended to eliminate common-sense observations that mean so much in the learning that occurs in all areas of life. The psychotherapeutic process is both simple and complicated. In being scientific, we demand studies so rigorous, to prove the obvious, that no one is able to devise them. Who demands a study to prove whether a university education leads to change in students exposed to it? Further, we take hypotheses which had some value as such, and make them rigid dicta that are expected to stand forever unchanged. Freud altered his views, by and large, throughout his career. Many psychoanalysts who followed him took his tentative hypotheses as established gospel, and considered all efforts to change them as heretical. Theoreticians in psychotherapy have understandably sought to reduce the pathological factors present to the smallest possible number, seeing all human neurosis through the framework of one or another over-simplified theory. The Procrustean bed of Oedipus cannot begin to accommodate the complex sources of disease and behavioural disorder that confront psychotherapeutic clinicians. We must avoid excessive generalisation and undue simplification. If there is a universal rule about human behaviour and pain, it is that character is so complex and human interactions so idiosyncratic that useful psychotherapy demands an entirely individual approach to each patient. We must avoid automatism, and retain our individual styles in approaching our individual patients, with their highly individual discomforts and disorders.

We have often carried diagnosis to extremes whereby a popular current way of looking at a common difficulty makes us see something esoteric in that which is not. In the past two decades the unhappy and regrettable ways in which stresses and lacks in Western society have moulded people, especially young people, have made us designate disorders or syndromes which we then discover on all sides. For a time everyone is hysterical, then passive–aggressive, then narcissistic, then borderline, next whatever comes along. Different experts propose different approaches for dealing with those who demonstrate hallmark symptoms of these 'new' disorders. It is doubtful that those approaches contribute much that is new, and they may divert the therapist from his most useful stance – that of an interested, enquiring, empathic, informed and open-minded clinician.

The struggle in psychiatry with the tendency to divide the person into body and mind has been a long and difficult one (Eisenberg, 1986). As a physician training in psychiatry in the 1950s I was exposed to two quite opposite views in regard to serious depressive disorders. Clinicians who were either psychoanalysts or else psychiatrists who felt that the only fundamental treatment was psychoanalytically oriented psychotherapy believed that severe depression was entirely a psychological matter, despite the fact that vegetative signs and behavioural symptoms of all seriously depressed patients were the same. The obvious need for organic (that is, biochemical and neurophysiological) explanations of the signs and symptoms was not seized upon. We used electroshock when the severity of the disorder demanded it, but with regret and often with disparaging references to 'the little black box'. Other clinicians, understanding that the depressed state must have biochemical underpinnings, prescribed biological treatments only. They considered it misguided and contra-indicated to 'waste time' talking to patients who suffered from such biological disorders, even when the cause was seen to be 'reactive' rather than genetic and familial, that is, 'constitutional'.

There has been a considerable improvement in this dichotomous situation. Today many psychiatrists are prepared to offer both biological and psychotherapeutic treatments to such patients. They hold that serious depressive disorder can arise in various ways. There may be a strong constitutional imperative or, at least, vulnerability, or it may result from the effects of "the slings and arrows of outrageous fortune". Whatever the aetiology, it is a situation in which biochemical change has occurred in the brain. To shorten the duration of pain, to forestall the possibility of violent behaviour, biological treatments (ordinarily chemical) are often or usually indicated. At the same time, some appropriate psychotherapy is equally indicated to deal with numerous factors: low self-esteem, the psychosocial causes that contributed to the development of the disorder, and, most important, the qualities of character that helped create the problem and threaten to do so again if untreated.

Such a multidimensional approach to psychiatry sees the presence of a psychotherapeutic component of treatment as not only acceptable, but essential. Psychotherapy must be recognised today as the potent tool that it is, one that does not exist in a vacuum: a flexible, variable, individually tailored treatment that takes its place as one amongst important equal companion treatments.

The essence of psychotherapy within psychiatry

What then is an appropriate psychotherapy for psychiatrists today? Often in the past, psychiatric psychotherapists have claimed to be super subspecialists, and have disparaged other than their own small area of special interest, be it psychoanalysis, family therapy, group therapy, behaviour therapy, or cognitive therapy. As I have pointed out elsewhere (Greben, 1984), it appears that most practitioners are more flexible and use more varying approaches than they imply publicly. Still, many therapists have restricted themselves to one technique only and this is as unsatisfactory as when a general psychiatrist is familiar with only one antidepressant or one major tranquilliser.

The general public has often been mystified by our language and our excessive contractions, but so have educated people in a variety of fields and professions. Somehow, our ways of understanding people must be less different than they have thus far been from the ways in which people have always been seen. We cannot improve upon Shakespeare and Dickens and Tolstoy, in terms of how a person is to be understood. That is, we must in the end return to everyday language and everyday formulations. For when we cannot be understood by intelligent people outside our own profession, then in truth we are not being understood by one another, and that in turn means that we are not being understood by ourselves.

What, then, are the implications of all this for psychotherapy in psychiatry? I would say that the following principles obtain:

- There can be no psychiatry without psychotherapy. In one form or another, psychotherapy is an essential treatment method, among numerous others, that are the tools of psychiatry.
- There is no single superior psychotherapy. More intensive work is better for some patients and worse for others.
- A psychiatrist needs to be competent in the use of psychotherapy and must be equally competent in the use of biological treatments, which currently largely means medications. If his training is deficient in this area, then he must have a colleague to whom he can refer his patients for such consideration.
- There is no reason to hesitate to combine biological treatments with psychotherapy, since the former in many instances will shorten the painful period for the patient, lessen the danger of suicide, make admission to hospital less often necessary, and render the patient better able to engage in the psychotherapeutic undertaking.
- A deep interest in psychotherapy does not mean that a psychiatrist should become distant or alienated from his medical colleagues. He should see himself as first a medical person, then a specialist in mental and emotional disorders and then a person with a particular interest in psychotherapy.
- Each of the various ways of applying psychotherapeutic principles has its own merit and value. Psychiatrists should be aware of the value of a therapist's meeting with more than one person – a married couple, part of or a whole family, or groups that have any of a variety of things in common.
- At the heart of all psychotherapy is the need of people in crisis to be heard, understood and helped. Therapists should be what patients need them to be: empathic, interested, concerned, reliable, respectful, and resourceful. They need to work hard at what they do, and not leave all the effort to the patient.
- The patient needs to be understood. The therapist needs to understand. On neither side is it necessary for that understanding to be perfect. The imperfection of the therapist will in the end help the patient to deal with the tendency toward idealisation of the therapist.
- In deeper psychotherapeutic work, attention to and discussion of what happens between the two participants is essential if the greatest possible degree of change is to eventuate.
- In addition to addressing symptoms, should they choose to do deeper work, psychiatrists will deal with

the underlying modes of behaviour and ways of relating to others which are best described by the word 'character'. The analysis of all aspects of character gives deeper forms of psychotherapy their greatest interest, and provides both therapist and patient with their greatest reward.

Isaac Bashevis Singer (1985), commenting upon a writer's work, said: "We always love to discuss and reveal character because human character is to us the greatest puzzle. No matter how much you know a human being you don't know him enough. Discussing character constitutes a supreme form of entertainment."

In a comparable way, attempting to understand the characters of our patients is the most challenging and entertaining aspect of the work of psychotherapists. To be humane, real people engaged in the work of psychotherapy, whether frequent and deep, or occasional and superficial, we must know and keep in mind the character of the patient, as well as his and our own humaneness. If we manage this, we will succeed in making and keeping psychotherapy, both today and tomorrow, the useful, important, even essential part of psychiatry that it must always be.

Pathology, Phenomenology and the Dopamine Hypothesis of Schizophrenia

P. J. McKENNA

The dopamine hypothesis of schizophrenia implies that positive schizophrenic symptoms should be understandable by reference to brain structures receiving a dopamine innervation, or in terms of the functional role of dopamine itself. The basal ganglia, ventral striatum, septo-hippocampal system, and prefrontal cortex, sites of mesotelencephalic dopamine innervation, are examined and it is argued that their dysfunction could form the basis of particular schizophrenic symptom classes. The postulated involvement of dopamine in reinforcement processes might further assist such interpretations. This type of analysis can be extended to other categories of schizophrenic psychopathology.

The leading view on the pathogenesis of schizophrenia, that a functional dopamine excess underlies some symptoms of the disorder, originated in observations that dopamine agonist drugs could induce a schizophrenia-like state, while therapeutically effective neuroleptic drugs were invariably dopamine antagonists (Carlsson & Lindqvist, 1963; Van Rossum, 1966; Randrup & Munkvad, 1967). The dopamine hypothesis gained ground with the systematic exploration of these effects (Snyder *et al*, 1974; Carlsson, 1977; Johnstone *et al*, 1978), which also indicated an involvement only in the productive, positive symptoms and not in those of the negative symptom defect state. A subsequent search for indices of dopamine excess in schizophrenic brains (see Mackay *et al*, 1982) has recently culminated in the demonstration of increased receptor binding in drug-free (Crawley *et al*, 1986) and drug-naive (Wong *et al*, 1986) patients. If confirmed, these findings strongly imply that some schizophrenic symptoms should be understandable in terms of structural and functional aspects of brain dopamine projections.

Structurally, the ascending dopamine pathways arise from the partly continuous midbrain A8, A9 and A10 cell groups, show a complex pattern of overlap in their terminal fields, and are currently considered to represent a single 'mesotelencephalic' system (Bjorklund & Lindvall, 1984). Two gross subdivisions are nevertheless retained: in the rat a 'mesostriatal' branch projects to the basal ganglia and some affiliated structures. The other, 'mesolimbocortical', branch innervates restricted parts of the limbic system and also reaches cortical areas corresponding to the prefrontal and anterior cingulate cortex of higher mammals. A similar pattern of innervation appears to be followed in primates and man, with the possibility of additional significant projections to parts of the temporal lobe cortex (Brown & Goldman, 1977; Bjorklund *et al*, 1978; Farley *et al*, 1978; Scatton & Zivkovic, 1984).

Functionally, the mesotelencephalic dopamine system has invariably been considered to exercise some diffuse modulatory function distinct from classical neurotransmission (Hornykiewicz, 1976; Bjorklund & Lindvall, 1984; Bloom, 1984). The further characterisation of this function, however, has involved the discipline of experimental psychology. Following Olds & Milner's (1954) discovery of the rewarding properties of electrical brain stimulation, it soon became established that catecholamine systems were crucially involved (see Crow *et al*, 1972; Wise, 1978). At present it seems clear that dopamine, either alone (Mason, 1984) or in co-operation with other transmitter systems (Crow & Deakin, 1985), mediates the reinforcing effects of brain stimulation, and it may govern at least some aspects of reinforcement under natural conditions as well (Wise, 1982; Beninger, 1983; Mason, 1984). This evidence has survived numerous attempts at refutation and requires accommodation in any theory of dopamine's behavioural role (Deakin, 1983).

The structural interpretation of schizophrenic symptoms began with Kleist (see Fish, 1957; Kleist, 1960) who, long before the discovery of dopamine, argued for the presence of signs of basal ganglia and frontal lobe pathology. Several subsequent authors (e.g. Stevens, 1973, 1977; Crow *et al*, 1977; Iversen & Fray, 1982) have attempted to relate schizophrenic symptoms to these and other sites of mesotelencephalic dopamine innervation. The complementary view, of schizophrenia as a disorder of reinforcement, dates from Stein & Wise's (1971) proposal of progressive damage to a central reward system. This approach, applied specifically to positive symptoms, has been adopted by Crow and co-workers (Crow *et al*, 1977; Crow, 1979) and elaborated further by Miller (1981, 1984). But, while some aspects of the dopamine hypothesis have been the subject of detailed investigation (e.g. see Joyce, 1983; Creese *et al*, 1983; Mason, 1984), its application to the phenomenology of schizophrenia remains uneven, haphazard and unintegrated with developments in neuroanatomy, neuropsychology and learning theory. This review, therefore, summarises current knowledge on dopamine-innervated brain structures, examines ways in which their pathology might be related to schizophrenic symptoms, and argues that in each case independent findings support the conclusions reached.

The basal ganglia

Animal experimental findings

The largest site of forebrain dopamine innervation is the basal ganglia. The mesotelencephalic dopamine system provides dense fibre distributions to the caudate nucleus and putamen (jointly termed the striatum), and there are additional sparser projections to other basal ganglia core structures, the globus pallidus and subthalamic nucleus (Bjorklund & Lindvall, 1984).

The major input to the basal ganglia is the entire cerebral neocortex; this projects in an orderly way upon the striatum, and a large through route, the striopallidal pathway, connects this with the premotor regions of the frontal lobe (Graybiel & Ragsdale, 1979; Nauta & Domesick, 1984). The obvious anatomical inference, that the basal ganglia have some motor function, is supported by considerable physiological evidence (Marsden, 1982). At the same time, certain inadequacies in such a view are recognised: both lesion (Teuber, 1976; Stern, 1983; Divac, 1984) and electrical recording (DeLong *et al*, 1984; Evarts & Wise, 1984; Rolls, 1984) studies associate the basal ganglia as much with the learning and performance of various behavioural tasks, as with the simple motor control of these. Overall theories of basal ganglia function have tended to be inexplicit, or have pointed to a role in the specifically volitional aspects of motor behaviour (Villablanca & Marcus, 1975; Divac & Oberg, 1979). According to Marsden (1982, 1984), the basal ganglia may ultimately be responsible for "the automatic execution of learnt motor plans".

Dopamine has complex effects in the basal ganglia, but overall has been argued to facilitate the passage of information round the striopallidal circuit (Groves, 1983). Behaviourally, severe dopamine depletion induces a profound hypokinesia (see Joyce, 1983; Mason, 1984) which characteristically is temporarily abolished by intense adverse stimulation (for instance, immersing rats in freezing water or placing them among cats!). Dopamine agonist drug stimulation, on the other hand, induces a general locomotor hyperkinesia which quickly gives way to the phenomenon of stereotypy, where there is an increasing repetition of one or a few responses from the normal repertoire of the animal (Iversen, 1977): the normal variability of behaviour gradually diminishes and is replaced by the incessant performance of simple acts like sniffing, biting or rearing.

The conceptualisation of dopamine as reinforcement is by no means incompatible with such findings. A number of authors (Iversen & Koob, 1977; Wauquier, 1979; Miller, 1981) have noted similarities between behaviour termed 'voluntary' and that referred to as 'instrumental' in learning theory, and have suggested that the basal ganglia might function generally as an effector system for instrumental learning and performance. Instrumental behaviour is of course governed by reinforcement, and recent formulations stess not only the familiar trial-to-trial 'learning' effects of reinforcement, but also its moment-to-moment 'performance' functions. Reinforcers are considered able to energise responding directed towards themselves, resulting in the occurrence of relatively unstructured approach responses (*vide infra*) or of already learnt formal instrumental acts (Bolles, 1975; Gray, 1975; Bindra, 1978) – this latter function perhaps being not far removed from a facilitation of Marsden's (1982, 1984) "automatic execution of learnt motor plans".

Human basal ganglia pathology

The cardinal signs of disturbed basal ganglia function in man are Parkinsonism and the involuntary movement disorders. In addition, a variety of basal ganglia disease states are accompanied by cognitive impairments; this echoes animal findings, though the extent to which the basal ganglia rather than other structures are involved remains controversial (Marsden, 1980; Cummings & Benson, 1984).

In Parkinsonism, the loss and slowing of voluntary movement is thought to reflect a relatively pure basal ganglia hypofunction, with features like tremor and rigidity being attributable to the abnormal release of function in distant brain sites (Marsden, 1984). Parkinsonism is typically the result of reduced striatal dopamine availability, and there is no dispute that it is analogous to animal hypokinetic syndrome that follows dopamine depletion.

The involuntary movement disorders consist principally of chorea, athetosis and dystonia. Despite considerable phenomenological differences, these are usually considered to be the closest human counterpart to the animal syndrome of stereotypy. As with stereotypy, striatal dopamine excess is commonly implicated in the genesis of involuntary movements and has been argued to be the common denominator of choreo-athetosis in a number of disease states (Klawans & Weiner, 1976; Calne, 1982).

Basal ganglia dysfunction in schizophrenia?

Irrespective of any basal ganglia role in cognitive functioning, the dopamine hypothesis clearly predicts that among the clinical manifestations of schizophrenia, involuntary movements should be seen. Controversy over this issue predates the discovery of dopamine by decades. In his original description of catatonia, Kahlbaum (1874) recorded abnormal movements which so resembled those of basal ganglia disease that later authors (Marsden *et al*, 1975) felt obliged to explain them. Kraepelin (1913) noted the occurrence of "peculiar, sprawling, irregular, choreiform, outspreading movements" in several of his patients, these being recorded in detail by Farran-Ridge (1926). Bleuler (1911), on the other hand, considered that true choreo-athetosis was rarely, if ever, seen in schizophrenia.

Contemporary surveys of psychiatric populations have revealed the presence of tardive dyskinesia-like movements in up to 14% of non-geriatric patients never exposed to neuroleptic treatment (Jones & Hunter, 1969; Crane, 1973); in two of these the frequency approached that seen in treated patients (Demars, 1966; Brandon *et al*, 1971). These studies, however, all failed to specify a schizophrenic diagnosis, to control for age, or to exclude organic disease.

Two recent detailed investigations may be more decisive. Owens *et al* (1982) examined 411 chronically hospitalised patients fulfilling research diagnostic criteria for schizophrenia, 47 of whom appeared never to have been exposed to neuroleptic treatment. All patients were assessed for movement disorder twice, using rating instruments, and under blind conditions. At least half showed evidence of tardive dyskinesia-like involuntary movements, and the authors were unable to demonstrate significant differences between treated and untreated patients in the prevalence, severity or pattern of these.

Rogers (1985) examined 100 patients admitted to chronic care prior to the availability of neuroleptic drugs, at least 92 of whom were diagnosed as suffering from schizophrenia. In order not to pre-empt classification as neurological or psychiatric, motor abnormalities were recorded descriptively, in non-prejudicial categories. Amidst many more elaborate phenomena, simple chorea- and athetosis-like disorders were found in 50–75% of patients, including eight who had never received neuroleptic treatment. Furthermore, in nearly 40%, the presence of similar abnormalities had been recorded before any use of neuroleptics:

> For 38 there were more detailed descriptions of various movements which could be brief, random or continuous: having frequent tic-like movements of mouth, cheeks and head; numerous "schizophrenic" tics; their head occasionally jerking back or moving suddenly from one side to another; keep twitching their shoulders, hands and arms; having constant movements of hands fingers and feet . . . or sustained, spasmodic movements: continually squirming about in bed; exhibiting a strange, writhing, snake-like movement of the limbs combined with grimaces which strongly resembled a choreo-athetosis; insane mannerisms such as contorting their body; or insane athetoid movements.

Individually, it is possible to dispute these findings, but taken together they make it difficult to resist the conclusion that involuntary movements indistinguishable from those of basal ganglia disease sometimes form part of the untreated symptom picture of schizophrenia. Such abnormalities appear generally minor, are associated principally with chronic disease, and are probably promoted by neuroleptic treatment (Owens, 1985), though this is by no means a prerequisite. Finally, their occurrence appears inextricably bound up with volitional motor disturbances of an altogether more complex nature, a theme which is developed further in the next section.

The ventral striatum

Animal experimental findings

The mesotelencephalic dopamine system provides projections to two subcortical structures, the nucleus accumbens and olfactory turbercle (Bjorklund & Lindvall, 1984), which until recently were of obscure affiliation. Over the last decade, however, it has become clear on a number of grounds that they should be regarded as part of the neighbouring caudato-putamen (Heimer & Wilson, 1975; Swanson & Cowan, 1975); along with the ventromedial sector of this structure, they are now considered to form a distinct basal ganglia subregion, the ventral striatum.

The ventral striatum receives its principal inputs from limbic system sites, notably the hippocampus and amygdala (Heimer *et al*, 1982). Its subsequent projections parallel and overlap with the classical striopallidal pathway at every step to reach ultimately frontal regions anterior to the premotor cortex

(Heimer *et al*, 1982; Graybiel, 1984). Functional information derives almost exclusively from studies employing selective striatal dopamine alterations. In rats, ventral striatal dopamine depletion has no overall hypokinetic effect, but alters locomotor patterns, impairs exploration and investigation of novel stimuli, and leads to various other difficulties suggesting impaired co-ordination of different classes of behaviour (Koob *et al*, 1978; Robbins & Koob, 1980; Iversen & Fray, 1982; Wallace *et al*, 1983). Conversely, dopamine agonist stimulation results in a state of locomotor hyperactivity relatively uncontaminated by stereotypies, and it has been argued that there is a complex partitioning of such functions between dorsal and ventral striatal sectors (see Joyce, 1983; Mason, 1984). In primates, in addition to hyperactivity, searching, startle responses and the repetitive adoption of inappropriate postures are seen (Dill *et al*, 1979).

Such findings have been virtually unanimously interpreted as indicating a ventral striatal involvement in the motor expression of emotional and motivational processes (Iversen, 1980, Mogenson *et al*, 1980; Iversen & Fray, 1982). The ventral striatum, these authors argue, controls the motor aspects, particularly the head, whole body and locomotor movements, of functions which mediate the animal's arousal by, orientation towards, and investigation of significant stimuli in the environment. This is the behaviour which invariably precedes the organisation of specific motor responses to such stimuli.

As has been noted (Crow, 1973; Iversen & Fray, 1982) such concepts are essentially similar to those of incentive and approach in learning theory. In various theoretical formulations (Mowrer, 1960; Bolles, 1975; Gray, 1975; Bindra, 1978), stimuli associated with reward acquire the ability to induce a state of motivational arousal, which in turn generates the flexible, relatively unstructured responses of approach. These serve to guide the animal towards the motivational stimulus and give way to formal instrumental responses as this is reached. According to Gray (1975), approach behaviour depends ultimately on a positive feedback mechanism and this, he argues, is mediated by reinforcement.

Human ventral striatal pathology

The ventral striatum has been linked to human disease states only in a preliminary way, as expected to phenomena in some way related to those of basal ganglia disease. A hypofunction has been implicated in some of the more subtle akinetic abnormalities in Parkinson's disease (Young & Penney, 1984). Among hyperfunctional phenomena, tics show an intimate association with basal ganglia disorders (Jung & Hassler, 1960; Weingarten, 1968), and various authors (Fahn, 1982; Nauta, 1982; Young & Penney, 1984) have speculated on the involvement of the ventral striatum in their pathogenesis.

In addition, some basal ganglia disease states appear to be marked by other hyperfunctional phenomena related to, but going beyond, those of chorea, athetosis and dystonia. In encephalitis lethargica, Von Economo (1931) described intricate, elaborate, often grotesque paroxysms of motor activity accompanying the insidious development of Parkinsonism. Wilson (1940) also drew attention to "more leisurely and complex movements, distinct from chorea, which recall those of tic but are slower, more purpose-like and even more compound". With l-dopa therapy, a massive potentiation of this type of abnormality was observed to take place (Sacks, 1983). In the contemporary condition of tardive dyskinesia, numerous authors (Jones & Hunter, 1969; Mackay, 1982; Fahn, 1984; Lees, 1985) have described movements which are repetitive or rhythmical, rather than choreo-athetoid in nature. One widely used rating scale for the disorder (Simpson *et al*, 1979) even includes items for 'grimacing', 'caressing or rubbing face or hair' and 'crossing and uncrossing legs' – phenomena classed uneasily alongside the random, shifting, fragmentary movements of choreo-athetosis.

Ventral striatal dysfunction in schizophrenia?

The ventral striatum, by virtue of the dopamine hypothesis, has been repeatedly incriminated as a site of dysfunction in schizophrenia (Stevens, 1973; Crow *et al*, 1977; Matthysse, 1981; Iversen & Fray, 1982). At the same time, the resemblance between the elaborate, integrated motor phenomena that could reflect its dysfunction, and some of the catatonic symptoms of schizophrenia, has regularly struck phenomenologically minded authors (Farran-Ridge, 1926; Von Economo, 1931; Sacks, 1983; Sims, 1987). Combining these preclinical and clinical findings, therefore, it may be possible to arrive at interpretations of some fundamental catatonic phenomena.

Anatomically, the ventral striatum receives a selectively limbic afferentation, its connections overlap with those of the basal ganglia proper, and it is considered to mediate the motor expression of emotional and motivational processes. Contributing to a basal ganglia movement disorder, it might thus lend otherwise unremarkable involuntary movements a certain emotional toning, a motivational quality not ordinarily seen. In schizophrenia just such a symptom is occasionally encountered as parakinesia (Kleist, 1960), described by Fish (1957) as follows:

> Here the leading symptoms consist of fragmentary movements which resemble those of chorea, athetosis and the tics. Although they look like involuntary movements they can always be imitated and are partly reminiscent of expressive and intentional movements.

Functional studies suggest that the ventral striatum is concerned with the integration and strategic co-ordination of motor behaviour rather than the elaboration of individual responses. This has been considered clinically relevant to the occurrence of tics and other complex motor abnormalities. A catatonic symptom, mannerisms, however, has rather similar characteristics. Bleuler (1911) in fact stated that in many cases mannerisms could not be distinguished from tics. With the complex tics seen in l-dopa treatment of post-encephalitic Parkinsonism (Sacks, 1983) and in Gilles de la Tourette's syndrome (Marsden *et al*, 1983; Lees, 1985), which may also have a basis in dopamine excess (Devinsky, 1983), the differentiation from mannerisms becomes especially problematic. According to Rogers (1985), the two abnormalities may be phenomenologically one and the same.

But ultimately, it may be that the basal ganglia and ventral striatum govern different aspects of a single superordinate function, the learning and performance of instrumental behaviour under the influence of reinforcement. In animals, adventitious reinforcement results in a syndrome of 'superstitious' behaviour, where instrumental acts, often stylised or incomplete, are performed repetitively (Matthysse, 1981). In man, a dopamine excess affecting the two striatal sectors in a balanced way might give rise to a comparable phenomenon, with the appearance of largely normal-appearing goal-directed acts made abnormal by virtue of repetition. But this of course is a description of a catatonic symptom central to schizophrenia, which, years before the investigation of dopaminergic drug effects in animals, had already been given the name stereotypy (Bleuler, 1911; Kraepelin, 1913).

More detailed examination of dopaminergic drug actions provides independent support for a relative rather than absolute distinction between involuntary movements and catatonic symptoms. In rats, the behavioural response is stereotyped head, limb or whole body movements (Iversen, 1977); more elementary movements are not seen or are obtained only with difficulty (Waddington *et al*, 1983). In cats and dogs, a greater variety of phenomena begin to appear, and in monkeys the abnormalities range from simple tongue and lip movements, through nodding, bowing and rocking, to activities like opening paws in succession or following a fixed route repeatedly (Randrup & Munkvad, 1967; Ellinwood *et al*, 1973; Schiorring, 1981). The equivalent human syndrome, seen in stimulant-drug abusers, encompasses choreo-athetosis, simple repetitive movements, incessant tidying, grooming and mechanical activities, even the writing and destroying of hundreds of fraudulent cheques (Rylander, 1972; Lundh & Tunving, 1981; Schiorring, 1981; Lees, 1985). In short, as the evolutionary scale is ascended a central syndrome of stereotypy progressively diversifies, with involuntary movements at one end of the spectrum and, at the other, phenomena indistinguishable from schizophrenic stereotypies.

The septo-hippocampal system

Animal experimental findings

Prominent limbic projections of the mesotelencephalic dopamine system include those to the entorhinal cortex and lateral septal area (Bjorklund & Lindvall, 1984). It is clear, however, that these are components of a well defined structural complex with the hippocampus as its core, the septo-hippocampal system (Swanson, 1978). The hippocampus itself may also receive a dopamine innervation, though only indirect evidence exists for this (Bjorklund & Lindvall, 1984).

The septo-hippocampal system receives important inputs from sensory association cortex, the prefrontal cortex and the amygdala; its outputs reach the cingulate gyrus, the ventral striatum and the hypothalamus among other sites; its circuitry otherwise features a number of loop systems (Swanson, 1978; Gray, 1982; Graybiel, 1984). A huge body of experimental data has revealed no simple motor, sensory, learning or emotional functions, but has pointed instead to important modulations of behaviour at a fairly sophisticated level (Grossman, 1978; O'Keefe & Nadel, 1978; Gray, 1982).

The diverse theoretical approaches to septo-hippocampal function have recently been reconciled and integrated by Gray (1982): he proposes that the septo-hippocampal system acts quite generally to compare 'actual' with 'expected' in an animal's environment. On a moment-to-moment basis, the system receives 'actual' sense data via its sensory association area inputs, and matches these with 'expected'; that is, predictions based on previous experience generated in the cingulate and prefrontal cortex. When 'actual' and 'expected' coincide, the system functions passively, permitting continued elaboration of the current motor plan and passing on information that a match has taken place for storage elsewhere. But if, because of environmental change, 'actual' and 'expected' no longer agree, the septo-hippocampal system takes active control of behaviour: on-going behaviour is inhibited, arousal increases, and alternative exploratory and investigative strategies are instituted. This active state of behavioural inhibition constitutes an animal version of the human experience of anxiety.

The ascending monoamine systems provide a further important class of inputs to the septo-hippocampal system, and almost certainly exert significant modulatory effects (Gray, 1982; Deakin, 1983). In the context of Gray's theory, noradrenaline and serotonin serve to label incoming stimuli as 'important' or 'important, associated with punishment', enhance environmental checking, and bias septo-hippocampal operation towards behavioural inhibition. Dopamine (Gray, personal communication) is liable to have somewhat different effects. It may also act to label incoming stimuli as 'important' (perhaps as 'important, associated with reward') but, in line with its general reinforcement affiliations, it should antagonise mismatch detection and behavioural inhibition and promote matching and the passive facilitation of behaviour.

It is no accident that Gray's theory is constructed around the premise that animals form and verify predictions. This in fact represents the most important recent development in learning theory. It has been established beyond reasonable doubt that animals model, predict, or otherwise compute expectancies in procedures including habituation (Gray, 1975), classical conditioning (Dickinson, 1980) and instrumental learning (Mackintosh, 1983; Toates, 1986). In the latter two procedures the computations performed revolve principally around reinforcement; in particular, the degree to which stimuli and responses are predictive of reward and punishment.

Human septo-hippocampal pathology

Damage to components to the septo-hippocampal system in man figures prominently in the long term, largely anterograde amnesia seen in Korsakoff's psychosis (Victor *et al*, 1971) and following bilateral medial temporal lobectomy (Milner, 1970; Butters & Cermak, 1975). While this finding is unexpected on the basis of animal work, equally the amnesic syndrome is a far from straightforward phenomenon.

The outstanding deficit appears to be in retrieval, rather than the encoding and storage of information (Weizkrantz, 1978; Baddeley, 1982). As retrieval almost certainly involves systematic checking and evaluation (Baddeley, 1982) and is marked in the amnesic syndrome by interfering effects reminiscent of those seen after animal hippocampal lesions, a degree of reconciliation between the animal and human data can be achieved (Weizkrantz, 1978; Winocur, 1982; Gray, 1982).

The amnesic syndrome is also surprisingly circumscribed: affected patients show near-normal learning and retention in a variety of perceptual and motor tasks, their access to vocabulary and other classes of 'semantic' information remains intact, and the memory defects appear to be largely restricted to personal, autobiographical, 'episodic' events (Baddeley, 1982; Cohen, 1984). Some recent theorising emphasises the reciprocal interactions that must take place between 'episodic' and 'semantic' memory (Tulving, 1983). It has also been suggested that the amnesic syndrome may be best understood not simply in terms of memory, but as a disruption of certain processes in the formation, maintenance and expression of 'declarative' knowledge (Hirsh & Krajden, 1982; Squire, 1983; Cohen, 1984) – the propositional 'knowing that', stored factually, as opposed to the procedural 'knowing how', stored as instructions.

Septo-hippocampal dysfunction in schizophrenia?

The possibility that a specific disturbance of septo-hippocampal function may take place in schizophrenia is raised by its dopamine innervation and reinforced by recent neuropathological findings (Scheibel & Kovelman, 1981; Bogerts *et al*, 1985; Brown *et al*, 1986). Furthermore, a key aspect of Gray's (1982) theory is its application to human psychiatric disorders, not only anxiety but also depression and obsessional states. The question thus arises of how a dopamine excess might affect septo-hippocampal function, and what particular schizophrenic symptoms this might form a basis for.

Within the framework of Gray's (1982) theory, it is reasonable to suppose that dopamine, like other monoamine inputs, serves to label incoming stimuli as 'important', perhaps specifically as 'important, associated with reward'. A dopamine excess would then cause neutral stimuli to become erroneously identified in this way. But according to phenomenologists (Schneider, 1949; Jaspers, 1959; Sims, 1987), the abnormal attribution of significance to neutral events is at the heart of at least some classes of delusion. In the view of Jaspers (1959):

> A basic feature of the first experience of delusional meaning is "the establishment of an unfounded reference."

> Significance appears unaccountably, suddenly intruding into the psychic life. Later the identical experience of significance is repeated, though in other contexts. The trail is blazed and the preparedness for the significant experience then permeates almost all perceived contents.

This line of argument can be taken further. According to contemporary theory, animals model events, make predictions, compute expectancies; the verification of these may take place in the septo-hippocampal system; in man, this function becomes one of formation, maintenance and expression of 'declarative' knowledge. The unmistakable implication is that there exists a specific neuronal machinery for belief, a machinery which, furthermore, is liable to be undermined by dopamine excess: in Gray's theory (Gray, personal communication) dopamine may bias septo-hippocampal function towards its passive, checking mode of operation, where predictions are confirmed as matched. Miller (1984) similarly argues that dopamine acts to "set the threshold for inductive inference", an excess permitting associations which would normally be rejected as coincidental to become established in memory. In other words, the plausible effects of a septo-hippocampal dopamine excess might be not only to induce an erroneous attribution of significance – or delusional meaning – but also to promote the generation of abnormal inductive inferences – or delusional beliefs.

Independent considerations also argue for a septo-hippocampal role in delusion formation. The single 'positive' symptom of Korsakoff's psychosis, confabulation, may share aspects of its phenomenology with delusion. As noted by Kraepelin (1909), confabulations are held with "rock-like certainty"; sometimes they are adhered to tenaciously for long periods (Jaspers, 1959; Talland, 1961); their content may be grandiose, persecutory or even fantastic (Kraepelin, 1909; Talland, 1961; Berlyne, 1972). At times, in fact, it may be difficult to decide whether the false statement of a Korsakoff patient is a confabulation or a delusion (Cutting, 1978). Finally, the occurrence of isolated delusions in Korsakoff's psychosis is well documented (Cutting, 1978); conversely, occasionally seen in schizophrenia is the striking phenomenon of delusional confabulation (Kraepelin, 1913).

The prefrontal cortex

Animal experimental findings

The prefrontal cortex is commonly defined as the area of frontal lobe anterior to the premotor regions which has reciprocal connections with the mediodorsal thalamic nucleus (Nauta, 1971). Across a range of animal species, however, the mediodorsal projection field coincides with the major site of neocortical dopamine innervation (Bannon & Roth, 1983; Bjorklund & Lindvall, 1984), suggesting that the prefrontal cortex is a specific target of the mesotelencephalic dopamine system.

The prefrontal cortex is a site of ultimate convergence for cortical sensory association projections in all modalites (Jones & Powell, 1970) and also has close connections with the limbic system, basal ganglia, ventral striatum and premotor cortex (Nauta, 1971; Goldman-Rakic, 1984; Nauta & Domesick, 1984). Functionally, while extensive prefrontal lesions are followed by apathy, emotional changes and over-responsiveness to stimuli (Fuster, 1980), more detailed lesion and electrical recording studies (Warren, 1964; Mishkin, 1964; Fuster, 1980) have indicated a particular role in the elaboration of behaviours requiring a high level of cognition. There is evidence of specialisations of function within different prefrontal sectors, but the common theme of these may be involvement in tasks requiring choice from a repertoire of recurring familiar alternatives whose relevance to reward changes from trial to trial (Rosenkilde, 1979; Fuster, 1980).

The various general theories of prefrontal cortex function (see Stuss & Benson, 1985) all show tantalising similarities and point to some executive role involving the formation, monitoring and revision of behavioural strategies or central response sets. The formulation drawing most heavily on animal work, however, is that of Fuster (1980): he argues that the prefrontal cortex has a superordinate function of giving temporal structure to complex, goal-directed behaviour. By means of three subsidiary functions, the prospective anticipation of events (a proposal similar to that in Gray's (1982) theory), the retrospective holding of information, and the attentional control of interference, the prefrontal cortex assembles complex schemas for keeping behavioural sequences on course to their goals. These schemas are, above all, active and intentive in nature; there is a continuous analysis, updating and referring back of information to the overall plan to determine the individual responses most suitable at each step.

The dopamine projection to the prefrontal cortex has complex electrophysiological properties (Bannon & Roth, 1983; Glowinski *et al*, 1984). At a behavioural level, its effect appears to be essentially facilitatory: Brozoski *et al* (1979) found that dopamine depletion in a particular region of monkey prefrontal cortex reproduced the typical impairments seen after destructive lesions. The effect was specific to dopamine and could be reversed by systemic administration of dopamine agonists.

Even here, there are affinities with learning theory concepts. Central to instrumental learning is the relationship between stimuli and responses – the way in which presentation of a particular stimulus comes to elicit performance of a particular response. Although originally considered simple, a great deal of subsequent work has made it clear that this process must involve selective attention, expectancy analysis, and the formation of 'representations' between stimulus, response and reinforcer (Mackintosh, 1975, 1983). But these are just the functions which have, quite independently, been attributed to the prefrontal cortex; this has been noted and preliminary attempts at integration have been made (Pribram, 1973; Gray, 1982; Mesulam, 1986).

Human prefrontal cortex pathology

The consequences of prefrontal damage in man are well known as the frontal lobe syndrome. The psychomotor, emotional and social aspects of the clinical picture have been described in detail and have clear counterparts in the animal lesion syndrome (Lishman, 1978; Fuster, 1980; Stuss & Benson, 1985). At the same time, a group of cognitive abnormalities are recognised: thinking becomes concrete, narrowed in scope and lacking in inventiveness. Simple, familiar tasks continue to be peformed without difficulty, but behaviour requiring planning, and the active pursuit of prospective goals can no longer be sustained. If attempted, significant information is disregarded in a characteristic way (Luria, 1973; Fuster, 1980; Stuss & Benson, 1985). On formal testing, in procedures like the Wisconsin Card Sorting Test (Milner, 1963) frontal lobe patients learn the initial sorting principle without difficulty, but fail to adjust their strategy when this is unpredictably changed, despite continuous feedback that they are in error.

As in animals, the human prefrontal cortex shows evidence of regional specialisation of function (Lishman, 1978; Milner & Petrides, 1984; Stuss & Benson, 1985). In addition, the dominant-sided prefrontal cortex has particular verbal functions; patients with lesions here show reduced fluency and are unable to generate normal numbers of words in given semantic categories (Milner & Petrides, 1984). A subregion of dominant prefrontal cortex appears to have an even more specialised language function: lesions just anterior to Broca's area give rise to 'central', 'frontal dynamic' or 'transcortical motor' aphasia (Goldstein, 1948; Luria, 1970; Benson, 1979), characterised at its purest by impoverishment of vocabulary, reduction in the length and complexity of sentences, and difficulties initiating and sustaining narrative speech.

Prefrontal cortex dysfunction in schizophrenia?

The question of abnormal prefrontal function in schizophrenia was raised by Kraepelin (1913), Bleuler (1911) and Kleist (Fish, 1957; Kleist, 1960), has been re-opened in contemporary work (Oades, 1982; Levin, 1984; Cutting, 1985; Muller, 1985), and is recently the recipient of notable experimental verification (Weinberger *et al*, 1986). The way such a dysfunction would be reflected clinically, however – in particular, the positive symptoms a prefrontal dopamine excess might give rise to – has attracted relatively little attention, though amongst other things conceptual, verbal, and linguistic phenomena might be anticipated. A class of positive symptoms with such characteristics is of course recognised in schizophrenia as formal thought disorder.

In animals an important, perhaps superordinate, prefrontal cortex role is the formation, monitoring and revision of cognitive schemas for goal-directed behaviour. In man, there are involvements in analogous aspects of conceptual thinking. Dopamine has facilitatory effects (Brozoski *et al*, 1979) and an excess might therefore induce an abnormal heightening of this function. Explanations of the discourse abnormality in schizophrenic thought show intriguing similarities: the loss of direction by "any unifying concept of purpose or goal" (Bleuler, 1911), and the "inability to restrict, eliminate and focus on the task in hand" (Cameron, 1944) are reminiscent of an overfacilitated generation of goal-directed conceptual schemas. The abnormality of 'derailment', closely related to 'loss of goal' (Andreasen, 1979), could reflect an increase in the moment-to-moment monitoring and revision of these.

More substantially, it is clear that the dominant prefrontal cortex has particular verbal functions, and a subregion specifically linguistic functions. If a dopamine excess disturbed function here, clear-cut semantic and dysphasic abnormalities might be anticipated to follow. A well documented element of schizophrenic thought disorder is the tendency to use imprecise approximations to words (Cameron, 1944; Andreasen, 1979): a glove is called a "handshoe", a pen a "paperskate", a patient stated he "had menu three times a day". The occurrence of specific dysphasic signs in schizophrenia also appears well established (Morice, 1986). In addition to agrammatism, a feature of Broca's aphasia, Kleist (1960) described paragrammatism where speech remained fluent but contained multiple grammatical misuses. Paragrammatism and another well known schizophrenic phenomenon, neologism, are also seen in jargon aphasia (Butterworth, 1985; Howard, 1985), whose general similarities to thought disorder have attracted attention (see Rochester & Martin, 1979; Brown, 1981). But the relevant phenomena remain complex, and their categorisation as linguistic or conceptual remains controversial. In the words of Weinstein (1981):

> Speech contains ornate phraseology, pedantic redundancies and 'high sounding' malaproprisms. When one patient was asked what was wrong with him, he replied with "Well it has been suggested that there were certain oddities and restrictions, technically the activities of the student body, so to speak." Even when speech has improved and the patient no longer has neologisms, he tends to make unusual word choices. For example, one man commented on the 'congestion' of his speech, and another recalled having done a lot of 'verbal gambling' with words. When tested for ability to generate rhymes, alliterations, synonyms, antonyms and homonyms, patients produce strings of impressive sounding but inappropriate words. A woman 'rhymed' the following: "ovoid, ovum, spectrum, parallax, quadrangle, trigonometry, algebra." Some subjects speak officialese. The use of alliterations and assonances and an exaggerated rhythm may impart a poetic quality.

– a passage which is not, in fact, a description of schizophrenic thought disorder but was instead drawn from an account of the clinical features of jargon aphasia.

The available independent evidence tends to follow the theme developed here. Perhaps the best established abnormality in schizophrenic thought is overinclusiveness (Payne, 1973). Consistent with a prefrontal dysfunction, overinclusiveness has been considered to represent the inverse of concrete thinking (Reed, 1970; Schwartz, 1982); it is typically demonstrated using sorting tasks (Payne, 1973); in a recent review (Schwartz, 1982), it was concluded that its basis could lie in 'pigeon-holing' – or the adoption of central response sets. At a verbal level, in contrast to the inability to generate semantic category words seen with dominant prefrontal lesions (Milner & Petrides, 1984), schizophrenic patients show increased word usage and choose distantly related words (Payne, 1973). Finally, severe schizophrenic thought disorder is not always distinguishable from dysphasia (Faber *et al*, 1983), and while it does not equate with known regional syndromes, it has recently been argued to be consistent with disorder in an 'executive' speech centre – located in the dominant prefrontal cortex (Morice, 1986).

Conclusion

By examination of the effects of dopamine on different brain systems, and with the assistance of its conceptualised role as reinforcement, some interpretations of the extraordinary clinical picture of schizophrenia can be attempted. The relevant symptoms, however, are far from exhaustive, and if such an approach has validity it should have broader applications. A few tentative steps in this direction can be outlined as follows.

Some versions of the dopamine hypothesis propose that an episodic dopamine excess may be superimposed on a more fundamental dopamine deficiency state (Chouinard & Jones, 1978; Mackay, 1980), this manifesting itself in the negative or defect state symptoms of schizophrenia. The commonplace simultaneous presence of positive and negative symptoms might appear incompatible with such a view, but has precedent in that tardive dyskinesia and Parkinsonism can simultaneously co-exist (Gerlach, 1979). Deficiency in a transmitter whose overall role is one of facilitation of voluntary, motivated or instrumental behaviour is of course in keeping with the important negative symptom of lack of volition (Andreasen & Olsen, 1982). More specifically, dopamine depletion in the prefrontal cortex has lesion-like effects (Brozoski *et al*, 1979) and the resemblances between the frontal lobe syndrome and the schizophrenic defect state have been noticed from the beginning of the century (Bleuler, 1911; Kraepelin, 1913; Kleist, 1960). But most provocatively, the prefrontal cortex contains a distinct speech area, lesions of which produce a loss of syntactic complexity (Morice, 1986) and "a reduction of spontaneous speech, a curtailment of the amount and the range of narrative expression" (Fuster, 1980), abnormalities tantalisingly similar to the negative schizophrenic symptom of poverty of speech.

The mesotelencephalic dopamine system also provides projections to nuclei of the amygdala, the piriform cortex and the bed nucleus of the stria terminalis (Bjorklund & Lindvall, 1984), implying a significant modulation of the amygdaloid complex (Ben-Ari, 1981). Anatomically, the amygdaloid complex is an interface between sensory association cortex and the hypothalamus, it has functions in the co-ordination of emotional reactions to perceptual stimuli, and, of relevance to learning theory, it may process the affective qualities of reinforcing events (Kapp & Kesner, 1981; Mishkin & Aggleton, 1981). There is thus no doubt about its involvement in emotional processes, and the scope for application to the bizarre and incongruous mood accompaniments of active schizophrenic episodes is obvious. Furthermore, if the net result of an amygdaloid dopamine deficiency was to impair the co-ordination of emotional responses to perceived events, this might not be an unreasonable model for the negative symptom of affective flattening.

Finally, no examination of schizophrenic psychopathology would be complete without some statement on the baffling and perhaps most peculiarly schizophrenic symptom of all. One site of mesotelencephalic dopamine innervation so far given little consideration is the anterior cingulate cortex (Bjorklund & Lindvall, 1984). In primates, this appears to play a leading role in the voluntary initiation of vocalisation (Jurgens & Pratt, 1979), and has recently also been shown (Muller-Preuss *et al*, 1980) to have direct anatomical links with a region of the superior temporal gyrus known to be concerned with the recognition of species-specific phonation. These authors speculate that this connection between vocalisation-initiating and auditory-decoding areas might be important for vocal learning, or could, on a moment-to-moment basis enable the animal to 'subtract' its own on-going or intended vocalisations from the rest of the acoustic information reaching it. Depending on attentional needs, either self-produced sounds or the environmental background could then be screened out. If an analogous anatomical arrangement existed in man, if it were devoted to the particular species-specific vocalisations of speech, if its 'subtractive' function were deranged by a dopamine excess, might it not be verbal auditory hallucinations that would be the result?

Unravelling the Relationship between Genetic and Environmental Risk Factors in Psychiatric Disorders

L. R. GOLDIN, L. E. DELISI and E. S. GERSHON

Murray *et al* (1985) have proposed a method for using biological markers and information about family history to reduce the heterogeneity in a disease such as schizophrenia. They propose that families which are heavily loaded with illness are most likely to be segregating for a major locus and therefore should be used for studies of genetic marker or other biological traits that are thought to be related to a genetic etiology. They propose that patients without a family history (sporadics) of an illness should be investigated for hypothesised environmental components since they are the cases where environmental factors are most likely to play a large role. They give an example from their own data on Ventricular Brain Ratios (VBR) in a sample of schizophrenic twins (Reveley *et al*, 1984) where schizophrenic twins without any family history (FH−) of a major psychosis had significantly larger ventricles than did schizophrenic twins with a family history (FH+). They conclude that while there is a genetic determinant to ventricular size within the normal range, large ventricles reflect an environmental aetiology that is more important in sporadic cases than in those with a familial pattern to the illness. Subsequently, Reveley & Chitkara (1985) found that singleton schizophrenic patients who were FH− had a significantly larger VBR than did controls while FH+ patients had a mean midway between FH− patients and controls. While this is an attractive hypothesis for the structural brain changes seen in some schizophrenic patients, results of other studies are not consistent with these findings (Nasrallah *et al*, 1983; Schulsinger *et al*, 1984; Owens *et al*, 1985; DeLisi *et al*, 1986). For example, in our own data (DeLisi *et al*, 1986), 'familial' schizophrenics had larger ventricles than did controls and risk factors thought to be environmental (head injuries and birth complications) were found to be present in that sample.

The classification of patients into FH+ and FH− groups has been used in a number of other investigations of biological traits in psychiatric patients. For example, Sedvall *et al* (1980) found that FH+ schizophrenics had higher CSF 5-HIAA and HVA than did FH− patients. However, these were preliminary findings, the number of FH+ patients was very small, and the study has not been replicated. Baron & Levitt (1980) found that FH+ schizophrenics had significantly lower MAO activity than controls and FH− patients did not differ from controls. Here again, the sample was small and other investigators have not confirmed the finding (Belmaker *et al*, 1977; Duncavage *et al*, 1982; Maj *et al*, 1984).

Some of the problems with this methodology have previously been raised by us (DeLisi *et al*, 1985). These include: (1) the fact that this comparison assumes that a substantial number of cases have a non-familial aetiology; (2) some patients may not have enough available relatives to classify confidently as FH+ or FH−; (3) The definition of what constitutes FH+ is somewhat arbitrary; and (4) some FH− patients will be of the genetic type. In this paper, we discuss these criticisms in more detail and try to determine which strategies are most likely to be powerful in identifying risk factors that can separate psychiatric patients into more homogeneous groups.

Problems of dividing patients into sporadic and familial cases

Existence of a non-familial aetiology

It is well accepted that environmental factors do play a role in the development of schizophrenia. It is also clear that the symptoms of schizophrenia can be caused by drugs and other known environmental agents. However, we do not know the extent to which other *unknown* environmental factors cause schizophrenia. By dividing patients into FH+ and FH− groups, one assumes that the environmental factors of interest to the investigators are playing a *much* larger aetiological role in the FH− patients.

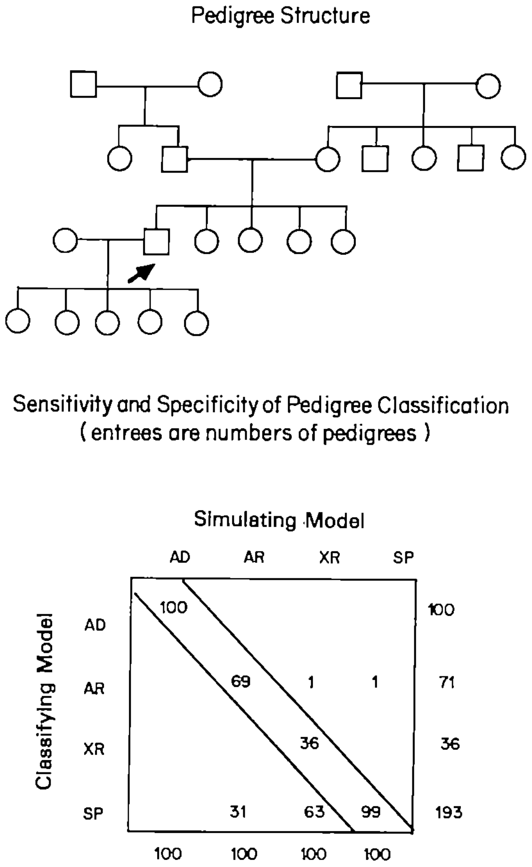
Sample size of relatives and definitions of FH+

If the family is very small, or information is only available on a few relatives, then it may not be possible to classify the family history type of the patient confidently. In addition, assumptions must be made about the disorders in relatives which should be considered as positive (i.e. genetically related to the disorder in question). It might seem reasonable to consider a spectrum of major psychiatric disorders in the relatives as a positive family history. However, some disorders may be common in the population and if many relatives were examined, it would not be unexpected to find additional cases. In such situations, it might be useful to classify patients taking the family size and population prevalences into account to determine if each family has significantly more cases than expected based on population frequencies. Furthermore, one must also consider how many relatives have not passed the age of risk at the time of data collection. Thus, it would also be necessary to know the age of onset distributions. Fortunately, data on population prevalences from recent epidemiological studies of psychiatric disorders are available (e.g. see Robins *et al*, 1984) although data on the prevalence of some of the milder disorders are not. For example, the population prevalence of schizotypal personality disorder, which is hypothesised to be part of the schizophrenia spectrum, is not known.

Heterogeneity of FH− group

Assuming that patients have enough relatives to be classified as FH+ or FH−, familial and sporadic groups, this classification is inherently heterogeneous because certain genetic mechanisms are expected to give rise to significant numbers of families that appear to be sporadic. A recent simulation study by Beaty & Boughman (1986) illustrates the effects of genetic heterogeneity for a disorder on the accuracy of subdividing a sample of families according to the most likely subtypes. They used retinitis pigmentosa as an example of a genetic illness with known heterogeneity. For the simulation, they chose a variety of pedigree sizes and structures ranging from small nuclear families to moderate size pedigrees of five generations and 20–30 individuals. For each pedigree, starting with one affected individual as the proband, they simulated 100 replicates each of four different models of inheritance (autosomal dominant, autosomal recessive, X-linked recessive, and sporadic). They then classified each simulated pedigree into one of the four categories based on which model had the highest relative likelihood in that pedigree.

They found that generally, families classified into the genetic types were homogeneous. For example, most of the families classified as autosomal dominant were correctly classified; that is, they had been simulated with the autosomal dominant model. The pedigrees classified as autosomal recessive were somewhat more heterogeneous. However, pedigrees classified as sporadic were the most heterogeneous group. On the whole, about half of those pedigrees classified as sporadic had been simulated with recessive inheritance. This was even true for pedigrees that were relatively informative (i.e. four generations and about 20 individuals). An example of typical results from this study is shown in Fig. 1. The pedigree used for this example has four generations and relatively large sibships. The 4×4 table gives the results of classification for the 100 pedigrees of this structure simulated for each of the four models. The numbers in the table indicate the sensitivity, i.e. the proportion of each simulated type correctly classified, and the specificity, i.e. the proportion of each classified type that were the correct type. Thus one can see that if the inheritance of the disease is autosomal dominant, both sensitivity and specificity are 100%; however, for the sporadic model, sensitivity is nearly 100% but specificity is only 51%. That is, only 99/193 pedigrees classified as sporadic had been simulated with the sporadic model. The remainder were pedigrees simulated with recessive inheritance misclassified as sporadic.



Pedigree Structure

Sensitivity and Specificity of Pedigree Classification (entrees are numbers of pedigrees)

FIG. 1. Example of simulation results from study of Beaty & Boughman (1986). One hundred pedigrees of this structure were simulated for each of the following models of inheritance: Autosomal Dominant (AD), Autosomal Recessive (AR), X-linked Recessive (XR), and Sporadic (SP). Each of the 400 pedigrees were classified according to the most likely mode of inheritance. The entrees in the 4×4 table are the results of simulated *vs* classified categories, the columns being the simulated type and the rows being the classified type. Measures of *sensitivity* are given by the diagonal/column total. Measures of *specificity* are given by diagonal/row total. For example, the AD model has 100% sensitivity and specificity whereas the SP model has 99/100 (99%) sensitivity and 99/193 (51%) specificity.

In our own previous simulation studies (Goldin *et al*, 1984), we were interested in trying to determine the accuracy of parameter estimates and hypothesis testing for different modes of inheritance. We also found that when the transmission was recessive or intermediate (i.e. heterozygote penetrance was 5–15%), the genetic parameters could not be reliably estimated and the major locus could not be consistently detected. We also found that many pedigrees simulated under these models looked sporadic (i.e. no other individuals were affected aside from the proband) which was likely to be the reason that the correct mode of inheritance could not be determined. For any real disorder, the heterogeneity of the group labelled sporadic will depend on the actual proportion of different types of families in the population and the size of the families being studied. Thus, it appears that if a recessive subtype of illness exists, many patients who have that subtype will come from families with no other affected relatives and would be classified as sporadic. The group called familial will only be heterogeneous to the extent that there exist different genetic types of illness.

This heterogeneity of familial and sporadic subgroups has consequences for biological risk factor studies. If there are some environmental factors in illness that play a much larger role in sporadic illness than in genetic illness, these can be detectable in FH+ *vs* FH− studies. However, large samples of patients may be required to detect such factors consistently since the sporadic subgroup will be a mixture of different aetiologies. On the other hand, biological traits that reflect genetic defects may be detectable in studies of familial patients.

Alternative approaches to clarifying the role of risk factors

We would argue that simply classifying patients into familial *vs* sporadic groups is a strategy that lacks power. Clearly the power could be increased if the familial risk could be quantified more exactly than simply as positive or as negative. One could then correlate a biological trait in a patient with the degree of risk in his family. Unfortunately, this may not be practical for most studies because family sizes are not usually large enough for accurate estimates of risk to be made. Another approach could be to classify patients into categories based on biological traits and then compare the morbid risks in relatives of the different subgroups. This strategy has proved useful in detecting clinical heterogeneity related to risk of illness in relatives in large family studies of affective disorders (Gershon *et al*, 1982; Leckman *et al*, 1983). Here again, relatively large numbers of families are needed in order to be able to estimate the risk in subgroups. In addition, for biological traits, it would be necessary to create some cut-off values in order to classify the patient. Often, cut-off values for a continuous trait are arbitrary and do not have any biological meaning.

Conclusion

Reveley *et al* (1985) argue that schizophrenia is analogous to coronary heart disease (CHD) where a rare monogenic form (familial hypercholesterolemia) exists in addition to the common form. Both share some of the same environmental risk factors, but these factors will play a much larger role in the common (non-familial) form. This may be analogous to schizophrenia. However, the ability to detect differences by comparing 'familial' and 'common' forms will depend on the role played by the risk factors in each group. For example, cholesterol levels might not differentiate familial CHD from non-familial since it may be a marker for a common final pathway leading to CHD in both types of patients. In fact, the rigorous study of the genetically determined receptor defects leading to familial hypercholesterolemia has provided a model for the mechanism behind dietary induced hypercholesterolemia. (It is thought high dietary cholesterol suppresses the number of liver LDL receptors which results in high serum cholesterol, which is the same end result obtained with decreased receptor numbers due to genetic defects.) With respect to schizophrenia, markers that directly reflect gene defects will contribute information about genetic subtypes of illness. However, markers that reflect environmental factors may not be detected by simply comparing sporadic and familial patients. Focusing studies on patients that are most likely to have a genetic form of the illness may clarify the underlying biological mechanisms and thus also define the roles played by environmental factors.

The Familial/Sporadic Distinction as a Strategy in Schizophrenia Research

S. W. LEWIS, A. M. REVELEY, M. A. REVELEY, B. CHITKARA and R. M. MURRAY

The rationale and limitations of discriminating between cases of schizophrenia with and without a family history are reviewed. It is concluded from the evidence available that, by identifying subgroups of greater aetiological homogeneity, the strategy can be a useful starting point for research into likely causes.

Research into cause in schizophrenia has lately been aided by standardised methods of interview and diagnosis and the arrival of a variety of techniques to measure, *in vivo*, aspects of cerebral morphology and function. As yet no clear answers have emerged, although it seems that such answers may now be within the scope of the combined efforts of epidemiological and biological psychiatry. Unfortunately, the search for causes is often hampered by inadequate reference to two important principles, one concerning the nature of schizophrenia and one the method of the search itself.

The first principle is that aetiological research must adhere strictly to the concept of schizophrenia as a *syndrome* defined by a pattern of symptoms and signs, without reference to the presence or absence of any presumed cause. This is the case in ICD-9 (WHO, 1978) but confusion arises if, as in the Research Diagnostic Criteria (Spitzer *et al*, 1975) and DSM-III (American Psychiatric Association, 1980), the diagnosis is explicitly disallowed when organic cerebral disease is known to be present. The relegation of those schizophrenias which arise in the context of cerebral disease to the status of "schizophrenia-like psychosis", or, in DSM-III terms, "organic mental disorder", leads to insurmountable circularity. Where is the sense in searching for the organic substrate of a disorder which is deemed only legitimately to exist in the absence of such a substrate? The problem has been thrown into sharp relief by the advent of the new brain imaging techniques, since the frequency with which schizophrenia is found to be accompanied by cerebral abnormalities depends on the sensitivity of the instrument used to look for them. To insist on excluding cases where the syndrome seems secondary to organic brain disease is to risk throwing out the aetiological baby with the nosological bathwater.

It is our view that schizophrenia is best viewed as the final common pathway of a range of different processes. This notion is not new (Mapother, 1937), but it brings us to the second general principle: the need to employ the right sort of hypothesis. If a cause is being sought, then testable hypotheses concerning the possible nature of that cause should form the basis of the search. Paradoxically, it is the very sophistication of many of the latest tools in neurochemistry and brain imaging that has led to the neglect of plausible hypotheses. The temptation is to use a novel technique as an end in itself, rather than to exploit it in testing a prediction. Computerised tomography (CT) is a case in point where, with a few exceptions (Owens *et al*, 1985), research has proceeded with little theoretical direction. The result is that we now know that a good proportion of schizophrenic patients show radiological appearances which differ, at least quantitatively, from normal, but we have little idea of why this should be so.

CT in schizophrenia

The significance of the CT scan research in schizophrenia should not, however, be underestimated. Variations between studies in selection and characteristics of patients and controls, and in the measurement techniques used, has meant that a consensus has been difficult to reach (Reveley, 1985; Smith & Iacono, 1986). Nonetheless, the weight of evidence points to lateral ventricular enlargement and cortical sulcal widening, in particular, being unexpectedly frequent in schizophrenia; these changes bear no relationship to the duration or type of treatment (Weinberger *et al*, 1979; Andreasen *et al*, 1982; Nasrallah *et al*, 1983; Kling *et al*, 1983; Williams *et al*, 1985; Owens *et al*, 1985) and are present at the start of the illness (Weinberger & Wyatt, 1982; Nyback *et al*, 1982; Schulz *et al*, 1983; Turner *et al*, 1986). The abnormalities speak, therefore, of cause rather than effect and can reasonably be assumed to antedate the illness. This being so, the CT research has yielded one of the few well-replicated findings which have a direct bearing on the aetiology of schizophrenia. Other such findings include the related observation that some cases of schizophrenia appear to be symptomatic of coarse brain disease, often environmentally mediated (Davison & Bagley, 1969), and the long-established evidence that relatives of schizophrenic patients have an increased risk of developing the illness themselves (Gottesman & Shields, 1982; Murray *et al*, 1986).

It is upon these few substantiated facts that testable hypotheses about underlying mechanisms should be based. As several mechanisms may be important, a fruitful starting point in their elucidation is to examine how these different findings interact. For example, is a family history of the disorder more or less commonly found in those schizophrenias secondary to coarse brain disease? Do patients with radiological abnormalities report past cerebral insults more or less frequently than those with normal scans? Consideration of the available evidence has led us to propose a strategy for future research (Murray *et al*, 1985) by which groups are identified in whom one or other of these aetiological indicators appears to predominate. We believe this to be a useful strategy, but it has found critics (DeLisi *et al*, 1985; Farmer *et al*, 1985; Eaves *et al*, 1986) and it is therefore timely to review not only the rationale behind it, but also its potentials and shortcomings in schizophrenia research.

Subdividing schizophrenia

Schizophrenia presents in a variety of different ways and leads to a variety of outcomes. This variation has resulted in many attempts to identify subgroups showing greater homogeneity. Traditionally, these attempts have been made using phenomenological criteria as in the classical Kraepelinian subtypes (WHO, 1978) and, more recently, the paranoid and non-paranoid types of Tsuang *et al* (1974), or those types with and without nuclear symptoms (Harrow & Quinlan, 1977), altered mood (Pope & Lipinski, 1978), or negative symptoms (Andreasen & Olsen, 1982). In addition, validity has been claimed for a number of subdivisions based on non-phenomenological variables, such as age of onset (Kay & Roth, 1961), premorbid personality (Strauss *et al*, 1977), neurological signs (Quitkin *et al* 1976), response to drug treatment (reviewed by Murray & Murphy, 1978) and prognosis (Langfeldt, 1956). Experience of syndromes in general medicine (e.g. cor pulmonale or epilepsy) suggests that subdivisions based solely on symptomatic or demographic data may have face validity but have little directly to say about the origins of the syndrome; in contrast, a single disease may present in a bewildering variety of symptomatological patterns (e.g. syphilis or diabetes).

The thrust of our argument is that the most rational basis for a valid subdivision of schizophrenia, and the one which is most likely to generate homogeneous groups for the purposes of fruitful research, is that based upon likely aetiological indicators rather than phenomenology. The main candidates are therefore indicators of genetic transmission and indicators of cerebral pathology.

Experimental subdivisions of schizophrenia according to the presence or absence of a family history have been used before (Shur, 1982; Baron *et al*, 1982; Kendler & Hays, 1982), as have subdivisions based on the presence or absence of structural pathology. Of the latter, Kleist's (1960) speculative classification remains the most complex, but Crow (1980) has suggested an aetiological classification into types 1 and 2 which has been influential despite remaining essentially untested. Several studies have examined the clinical correlates of lateral ventricular enlargement on the CT scan. In terms of illness features, only impaired neuropsychological test performance (Golden *et al*, 1980; Donnelly *et al*, 1980; Adams *et al*, 1984; Owens *et al*, 1985) and, perhaps, negative symptoms (Andreasen *et al*, 1982; Williams *et al*, 1985; Owens *et al*, 1985; Pearlson *et al*, 1985) stand as well-replicated associations with increased ventricular/brain ratio (VBR) in schizophrenia.

It is our interpretation of the evidence regarding the relationship between the presence of cerebral abnormality and the presence of a manifest family history in schizophrenia which lies behind our proposal. We contend that structural cerebral abnormality is statistically more common in those schizophrenic patients without an obvious family history. The evidence for an inverse relationship between these two factors is disparate but, we believe, strong.

Family history and cerebral abnormality

Where schizophrenia arises in the context of pre-existing cerebral disorder, a family history of schizophrenia is rare. This has been shown for the cases which follow cerebral trauma (Achte *et al*, 1969) and epilepsy (Slater *et al*, 1963). In their definitive review, Davison & Bagley (1969) concluded that schizophrenias with evidence of concurrent cerebral disease "usually occur in patients without genetic loading for schizophrenia". Kendler & Hays (1982) demonstrated that schizophrenic patients with a family history of schizophrenia were significantly

TABLE I

Published studies comparing CT findings in schizophrenia with and without family history (FH)

Reference	*Number in schizophrenic group*	*Positive FH*		*Control group*	*Measure*	*Reported significance of difference FH+ v. FH−*
		Definition	*Number*			
Campbell *et al*, 1979	35	Major functional psychosis in first-degree relative	18	None	Radiologist's rating	NS
Nasrallah *et al*, 1983	55	Schizophrenia in first-degree relative	8	Head-injury patients with 'normal scans'	VBR	$P<0.05$ larger in FH+

2. Not stated.

less likely to show an abnormal EEG than patients without a family history. Case reports of unsuspected discrete abnormalities on CT scan (Reveley & Reveley, 1983; Lewis & Mezey, 1985) suggest that a lack of familial predisposition characterises such patients.

Ten studies have now examined systematically family history in relation to CT scan abnormalities, particularly ventricular enlargement, in schizophrenia (Table I). Three studies (Campbell *et al*, 1979; Pearlson *et al*, 1985; Farmer *et al*, 1985) with small sample sizes found no relationship while the study of Nasrallah *et al* (1983) stands alone in reporting a *higher* rate of schizophrenia in the relatives of patients with large, compared with those with normal, ventricles. Five studies have found an inverse correlation between ventricular size and positive family history. In addition, Owens *et al* (1985) found an intriguing curvilinear relationship between "definite family history of schizophrenia" and VBR in 112 patients. The authors concluded that "a positive family history of schizophrenia is associated with normal ventricular size and that in those patients at extremes of ventricular size a family history is less common". Perhaps extremely small ventricles should also be regarded as pathological, as has been the practice in some post-mortem, pneumoencephalographic and CT studies in schizophrenia (Wildi *et al*, 1967; Gross *et al*, 1982).

The weight of evidence, therefore, suggests that in unselected populations of schizophrenic patients an *inverse* relationship exists between the presence of cerebral pathology inferred from clinical, radiological or post-mortem findings, and the presence of a manifest family history. This cerebral pathology is seen as the consequence of environmentally mediated processes. A causal continuum exists between these environmental factors at one pole and genetic factors (which manifest familial expression) at the other. This reciprocal relationship resembles the multifactorial model (Reich *et al*, 1972) of schizophrenia, with one important difference. The multifactorial model conceives of a liability to the disorder which is normally distributed throughout the population and is the sum of numerous genetic and environmental factors each of individually small, but additive effects. We would contend that the radiological data, for instance, imply that the environmental contribution often comprises single, relatively large, events. The possible nature of such events has been reviewed (Murray *et al*, 1985).

This is the rationale behind our proposal. The classification of cases into those *with* and those *without* a manifest family history will yield subgroups which, although not totally discrete, will be of substantially greater aetiological homogeneity. This will increase the chance of future research successfully identifying those genetic and environmental factors which are important in the cause of schizophrenia. Subdivision into familial and sporadic subtypes has been used fruitfully in other disorders whose epidemiology is not dissimilar from that of schizophrenia, such as epilepsy (O'Donohue, 1985).

We must emphasise that the familial/sporadic distinction is intended to be a pragmatic first step and is not, in itself, explanatory. Its value is heuristic, allowing the identification of groups of patients in which hypotheses can more readily be tested. Failure to appreciate that the strategy offers a means to test models, rather than being a model in itself, is part of the reason it has drawn criticism. Nevertheless, these, and more serious, criticisms should be examined.

Criticisms of the strategy

The first criticism is a theoretical one: "this proposal assumes, without sufficient evidence, that a significant proportion of schizophrenic patients have a non-familial aetiology" (DeLisi *et al*, 1985). In other words, it is wrong to suppose that non-genetic factors play a part in more than an insignificant fraction of schizophrenics. This *ex cathedra* statement is itself made with no evidence to support it. The plain fact is that all purely genetic models have been found lacking and none is sufficient to explain the way that schizophrenia is distributed within and between families. Furthermore, the genetic contribution to schizophrenia may be one of the few established aetiological facts, but its significance should not be exaggerated. It is of a similar order to that in medical conditions such as diabetes or hypertension (Kendler, 1983) and no one would suggest abandoning the search for non-familial causes in those conditions.

DeLisi *et al* (1986) have recently published in full the findings of the study which they previously quoted (DeLisi *et al*, 1985) in objection to the familial-sporadic strategy. We disagreed with their assertions then (Reveley *et al*, 1985) and inspection of their data substantiates our scepticism. Measures of lateral ventricular size were made on CT scan in 12 schizophrenic probands known to have at least one schizophrenic sibling. All the available siblings, of whom 12 had schizophrenia and 10 did not, were then scanned. Ventricular size was significantly greater in the schizophrenic patients than in their well siblings, thus replicating the results of Weinberger *et al* (1981) and Reveley *et al* (1982). The authors concluded that "increased ventricular size could represent an inherited vulnerability toward schizophrenia". This conclusion draws attention away from the truly interesting finding in their sample: a highly significant association, regardless of diagnosis, between ventricular enlargement and previous obstetric and childhood environment insults. In fact, all eight of the schizophrenic patients whose ventricles were larger than one standard deviation of a control mean had a history of either childhood head injury, birth complications, or intracranial infection.

Surely, then, to suggest from these findings that ventricular enlargement in schizophrenia represents an inherited vulnerability is mistaken. The conclusion can only be that pathological ventricular enlargement is a result of environmental rather than genetic influences. We do not dispute that environmental factors may also be of aetiological importance in some patients with a genetic predisposition. To do so would be misguided. Our point is that environmental factors assume greater importance in patients *without* a family history and that, if a search for these factors is to bear fruit, it should be directed primarily at such patients. The study of Schulsinger *et al* (1984) also confined itself to patients with a family history of schizophrenia. Their conclusion, in line with ours, was that environmental insults, in particular birth injury, predicted both large ventricles and schizophrenia and that these insults were of "direct aetiological significance".

Two further criticisms have been made that point to practical limitations of the strategy. The first is that some patients who actually have a genetic predisposition may be falsely classified as sporadic. The likelihood of this is highest if the patient's family has few relatives at risk, either due to small numbers or young age. Recently, Eaves *et al* (1986) made an elegant statistical exploration of the usefulness of the familial-sporadic distinction in aetiological research. They used a power analysis based on a series of more or less likely assumptions about the proportions of liability attributable to heritable and environmental factors. Their results suggested that, unless twins were used, large sample sizes would be needed before the familial-sporadic strategy could be expected to detect aetiological heterogeneity. However, as the authors went on to note, the fact remains that several studies of more modest size exist which have successfully demonstrated indicators of heterogeneity using the familial-sporadic approach. One explanation for the empirical success of the strategy despite the pessimistic projections of Eaves *et al* is that the aetiological model underlying their power analyses was mistaken. They assumed the polygenic-multifactorial model, in which environmental (as well as genetic) factors are of individually small, albeit additive, effect. As stated earlier we are dubious about this assumption, believing rather that some observations are more parsimoniously explained by the existence of environmental risk factors of relatively *large* individual effect. If this were so, it would serve to increase substantially the power of the familial-sporadic strategy and perhaps explain why it has already proven fruitful. The power could be increased further by discriminating the two groups subsumed under the sporadic heading: one group in whom positive radiological or historical evidence exists for past cerebral insult and a remaining group identified by exclusion, with manifest evidence neither of cerebral insult nor of familial risk. Nevertheless, possible artefacts arising from small family sizes cannot be ignored and may account for the failure of some studies to find an inverse relationship between family history and CT abnormalities (Campbell *et al*, 1979).

The second practical criticism is that there is no agreed definition for what constitutes a "positive family history" and that any definition is likely to be arbitrary. To some extent, this is so. Yet theoretical and practical considerations can guide the choice of such a definition, in terms of which disorders to include, in which relatives, and how the ascertainment should be made. From a theoretical standpoint, the disorders which are important in relatives are those for which good evidence exists of a genetic relationship with schizophrenia. Obviously, this will include schizophrenia itself, as well as schizoaffective disorders (Tsuang, 1979; Kendler *et al*, 1985). Furthermore, non-schizophrenic psychoses may occur more frequently than expected in the families of schizophrenic probands (Odegaard, 1972; Scharfetter & Nusperli, 1980). Evidence also exists that certain varieties of personality disorder, specifically schizotypal, are genetically related to schizophrenia (Kety, 1980; Baron *et al*, 1985), but these present problems of practical ascertainment. There is no doubt that direct family interview is the best method of detecting illness in relatives (Thompson, 1982), but family history data properly obtained from a related informant can be of adequate reliability (Andreasen *et al*, 1986). The reliability of such information is a function both of the severity of the disorder and the closeness of the relative, although schizotypal and related spectrum disorders have been assessed using the family history method (Baron *et al*, 1985). Empirical precedent varies as to whether to restrict consideration to illness in parents and siblings (Stephens *et al*, 1975), or all first-degree relatives (Scharfetter & Nusperli, 1980), or to include second-degree relatives (Owens *et al*, 1985; Reveley *et al*, 1984).

This lack of agreement makes it all the more important that researchers intending to use the variable of positive family history make explicit their defining criteria. It is hoped that forthcoming investigations of the impact that different definitions of this variable might have on the phenomenology, course and biological attributes of schizophrenia will enable more sensible selection from the differing definitions used to date (e.g. Table I). In the meantime, the dogmatic recommendation of any one definition cannot be justified. It is likely that the most restrictive definitions of positive family history would identify probands with the highest degrees of genetic liability. In this way, a 'narrow' definition might be the occurrence of schizophrenia requiring hospital admission in a first degree relative–parent, sibling, or child. A 'broad' definition, on the other hand, would be that including any psychiatric disorder, excluding uncomplicated drug or alcohol abuse, requiring the admission of a first or second degree relative to a psychiatric unit. Completed suicide would also be included. Broad definitions would reduce the chance of false negatives but inflate the danger of false positives and perhaps might best be used to identify, by exclusion, negative family history or 'sporadic' cases (Kendler & Hays, 1982). In large samples, narrow and broad definitions may be used in tandem to discriminate subgroups with different degrees of underlying liability in accord with multiple threshold models. In all cases minimum guidelines for ascertainment of family history should be followed: the interview of at least one related informant, with systematic recording of demographic information to include number and current age (or age at death) of relatives. This will allow subsequent age-correction and between-group matching for the age-corrected number of relatives at risk, if desired. Besides symptoms, diagnostic information for relatives should include age of onset, and method and agency of treatment, which may be supplemented by data from casenotes and, where appropriate, death certificates. Operational criteria for diagnosis in relatives are available for the Research Diagnostic Criteria (Andreasen *et al*, 1977) and have also been developed for spectrum disorders (Kendler *et al*, 1984).

Conclusions

Coherent threads can now be discerned in the unhappy tangle of research into the likely causes of schizophrenia. That genetic factors are important can no longer be disputed, while brain-imaging techniques have revealed cerebral abnormalities in a substantial proportion of patients. Our interpretation of the evidence available is that these abnormalities occur preferentially in patients without an obvious family history. Antecedent environmental insults such as encephalitides, head injury, and perinatal complications offer plausible mechanisms by which both cerebral pathology and the later illness itself arise in some patients. We have reviewed these mechanisms in greater detail elsewhere (Murray *et al*, 1985). The availability of exciting new techniques in brain imaging and molecular genetics is no guarantee that they will be used with appropriate rigour in schizophrenia research. In order better to test hypotheses about genetic factors on the one hand and environmental factors in the other we have proposed a simple classification of patients based on the presence or absence of a family history of similar disorder. Within the familial group, those individuals with schizophrenic first-degree relatives are most likely to repay research aimed at revealing genetic markers. Conversely, within the sporadic group, patients with radiological abnormalities offer the best chance of clarifying the nature and role of environmental factors. The puzzling epiphenomena found in an uncertain proportion of schizophrenic patients, such as developmental deviance, psychometric deficits, and neuromotor abnormalities, including those of lateralisation, may also yield clues in this group.

Expressed Emotion and Relapse in First Episodes of Schizophrenia
A Rejoinder to Macmillan *et al* (1986)

JIM MINTZ, LOIS MINTZ and MICHAEL GOLDSTEIN

Re-analyses of data presented by Macmillan *et al* (1986*b*) challenge their conclusions that high expressed emotion is not prognostically significant for the course of schizophrenia or unrelated to the level of behavioural disturbance prior to admission. Several equally plausible models of causal relationships between EE and duration of untreated illness are presented. We conclude that our re-analyses of the Macmillan data do not warrant premature closure regarding the significance of the EE variable.

> Comparison of relapse rates in the two Critical Comment groups revealed higher relapse/readmission rates in the group with a score of six or more ($P = 0.036$) . . . (Macmillan *et al*, 1986*b*).
>
> Neither of the two components of the CFI emerged from this study as important determinants of relapse/readmission significant at the 5% level . . . (Macmillan *et al*, 1986*b*).

Macmillan *et al* (1986*b*) studied the association between expressed emotion (EE) and outcome in a subsample of their first-break schizophrenics. The well established finding that high EE is a predictor of poor outcome has now been replicated with several major psychiatric disorders in several sociocultural settings. Studies of schizophrenics in England (Brown *et al*, 1972; Vaughn & Leff, 1976) and in the United States (Vaughn *et al*, 1984; Nuechterlein *et al*, 1986; Moline *et al*, 1986; Jenkins *et al*, 1986), and of depressed patients (Vaughn & Leff, 1976; Hooley *et al*, 1986), bipolar manics (Miklowitz *et al*, 1986) and obese patients (Leff & Vaughn, 1985) have all reported that patients living in homes with a high-EE relative are at increased risk of relapsing.

The above quotations present the reader of Macmillan *et al*'s paper with a difficult contradiction: despite finding a significant association between EE and outcome, the authors interpret their data as a failure to replicate this. Unfortunately, EE has become a focus of controversy in psychiatry: parents of schizophrenic patients have resisted what appears to be a new attempt to blame them for the illness, through the concept of stress as a cause of breakdown, while professionals who view the basis of schizophrenic illness as biological have argued against the allocation of resources to the study of psycho-social factors. Yet, this psychosocial variable has repeatedly demonstrated its utility as a predictor.

In this context, it is critical that responsible scientists evaluate, interpret, and present their data carefully and dispassionately. The paper by Macmillan *et al* is an important one, presenting new findings, coming from a respected research group, and forming part of a large and carefully conducted neuroleptic trial with a relatively unusual sample of first-break schizophrenic patients. It is likely to have a great impact on both professional and non-professional readers.

We believe that the fundamental assertion of these authors – that their results represent a failure to replicate the wellknown finding that EE is prognostically important for schizophrenia – is simply incorrect, and unwarranted on the basis of their own data. Furthermore, we are struck by a number of features of the analysis, presentation, and design of their data that reduce the credibility of their report.

Brief review of the Northwick Park design

The Northwick Park study, reported in four concurrent articles (Johnstone *et al*, 1986; Crow *et al*, 1986; Macmillan *et al*, 1986*a*,*b*), was primarily designed as a trial of neuroleptic medication versus placebo in the management of early schizophrenia. The larger study followed 120 patients who entered a randomised trial for two years, as well as a sample of 116 eligible patients who did not enter the trial and were followed in what is referred to as standard and presumably uncontrolled treatment.

The article in question reports on EE as a prognostic factor for a subsample of the patients – those residing with their families for three months prior to entry to the study, who were competent in English; patients in this study were drawn from both the randomised trial and from the standard treatment. It is important that the patients receiving standard treatment were a different population, with poorer prognostic features, as documented by Macmillan *et al* (1986*a*);

they had a longer period between the onset of illness and admission, longer stay in hospital, and less likelihood of employment after discharge. Even more important, the criteria for relapse were different: in the active and placebo treatment groups, the "main outcome variable . . . was relapse ascertained by the responsible clinician", whereas in the standard treatment group, relapse was defined only by re-admission – a much more limited criterion. Perhaps this is why outcomes were *better* in the standard treatment group, despite their having poorer prognostic indicators (Macmillan *et al*, 1986*a*).

In the major report on neuroleptic outcomes (Crow *et al*, 1986), data were presented only for those patients who entered the randomised trial. This is appropriate, since the patients in standard treatment were different from those in the randomised trial, and different outcome criteria had to be used. Macmillan *et al* (1986*a*), discussing differences in outcome between patients who entered the randomised trial and those in standard treatment, analysed all three groups separately. Even so, we regard the inclusion of standard and randomised patients in one analysis as questionable because the outcome criteria were meaningfully different.

Most importantly, in the EE study under discussion here, patients on active neuroleptic medication from the randomised trial and those in standard treatment were pooled together as one group. This is simply inappropriate, and it obscured differences between these groups that significantly affected interpretation of the results.

Why did Macmillan *et al* interpret their findings as a non-replication?

The primary method of analysis employed by Macmillan *et al* was life table or survival analysis with covariates; they acknowledge EE as a predictor of relapse in their survival analyses, and state that, "Comparison of relapse rates in the two CC groups revealed higher relapse/readmission rates in the group with a score of six or more . . .". They then dismiss this finding because the EE–relapse relationship was non-significant at the $P = 0.05$ level, when duration of illness prior to hospital admission and treatment group were included in a multivariate survival analysis. In their sample, EE turned out to be confounded (correlated) with treatment assignment (more patients from high-EE homes were assigned to placebo – a group with poorer outcomes), and with duration of untreated illness (high EE was associated with longer untreated duration – itself a poor prognostic indicator).

The confounding of EE and treatment

With regard to the confounding of EE and treatment assignment, Macmillan *et al*'s Table IV provided the data necessary for one re-analysis; we could not do a survival analysis, but were able to estimate the final two-year relapse percentages in each treatment group (Table I). The numbers in this table represent the percentage of patients who relapsed, excluding those lost to follow-up, while the numbers in parentheses represent the possible range of relapse rates when the cases lost to follow-up are included, with the lower figure representing the relapse rate if all the lost cases did not relapse, and the higher figure representing the relapse rate if all lost cases relapsed.

TABLE I
Relapse rates by EE and treatment group

	Treatment group		
	Active	*Standard*	*Placebo*
Low EE	50%	10% (8–25%)	60%
High EE	86% (67–89%)	46% (43–50%)	78%

There were only five patients in this sample who were lost to follow-up; these may have had any of 18 possible patterns of outcome. For example, the two in the low-EE standard-treatment group could have had three patterns of outcome (both non-relapsed, both relapsed, or one relapsed, one non-relapsed). The same is true for the two lost cases in the high-EE active-treatment group. Finally, the one lost case in the high-EE standard-treatment group could have had two outcomes (relapsed or not). Thus, there are $3 \times 3 \times 2 = 18$ possible ways in which these lost cases might have fared.

We analysed the data for all 18 possible outcomes, using a log–linear model with EE, treatment group, and their interaction. Fourteen of these yielded a significant EE effect at the two-tailed 0.05 level, and 17 were significant at the one-tailed 0.05 level (a one-tailed test is justified in view of the large body of prior research). The only analysis that was non-significant was based on the unlikely assumption that all three high-EE patients lost to follow-up had good outcomes and that both low-EE patients lost to follow-up relapsed. That analysis still yielded a one-tailed P-value for EE of 0.06. We conclude that confounding of EE with treatment did *not* account for the association between EE and outcome which Macmillan *et al* found.

The confounding of EE and duration of untreated illness

When a measure of 'duration of untreated illness' was included in the multivariate survival model, the significance of EE as a predictor of relapse/readmission was reported to be attenuated, and no longer significant at the 5% level. In fact, the significance of EE in a multivariate model which included treatment and duration was 0.07 (one-tailed test). It is unfortunately commonplace to interpret the 0.05 level as a firm dividing line between real and chance relationships.

In any event, the fact that the partial association of EE and outcome was non-significant – even if it were ultimately proven to be zero in the population when viewed in the context of these other variables – is in no way inconsistent with the view that EE plays a causal role in outcome. Figures 1–3 describe three causal models, which we have characterised as 'spurious correlation,' 'indirect causation', and 'mediating variable'. Each of these models includes EE, duration, and outcome, and each is consistent with the data of Macmillan *et al.*

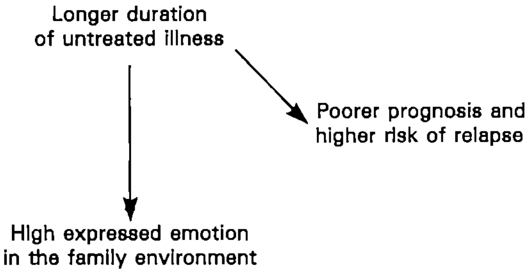

FIG. 1 Model I: spurious correlation.

In Fig. 1, the relationship between EE and outcome is spurious: it results from the fact that EE and outcome both have a common cause, and with this model, controlling for duration eliminates the relationship between EE and outcome. This appears to be the model assumed by Macmillan *et al*; it suggests that high EE is a reaction to a longer period of illness, and that the relationship between EE and relapse is simply a statistical artifact, explained by this confounding. This interpretation is certainly plausible and intriguing, and deserves further investigation.

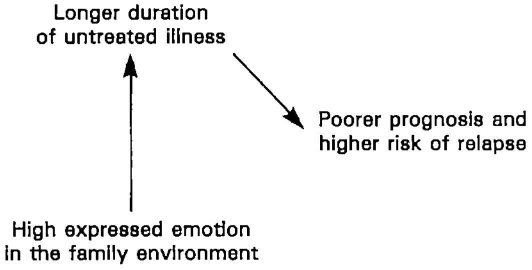

FIG. 2 Model II: indirect causation.

In Fig. 2, the causal relationship is simply reversed. This model acknowledges the causal importance of untreated duration for outcome, but assumes that high EE in the home itself is a factor that causes duration to be longer. How could this be? We offer a few hypotheses, noting that the measure of duration used by Macmillan *et al* was largely derived from reports by the relatives themselves – the same source used for the ratings of EE.

One plausible suggestion is that high-EE relatives are less likely to attribute to illness any deviance which occurs in their children prior to their first clear psychotic break, resulting in longer untreated durations and poorer outcomes. Alternatively, since the length of illness prior to admission was derived at least in part from relatives' reports, it is possible that high-EE relatives might simply report longer periods of illness than low-EE relatives, and that these reports would not be consistent with those of other informants. Perhaps high-EE relatives are more accurately sensitive to early signs of schizophrenia, or more easily bothered by mild signs of deviance, or perhaps these reports of earlier onset prior to treatment simply reflect another criticism of the patient – a characteristic that defines the EE status of the relative.

Any of these scenarios might underlie the causal model of Fig. 2. They are all consistent with a zero partial association between EE and outcome, when duration is controlled, but none imply that EE is either prognostically or causally insignificant.

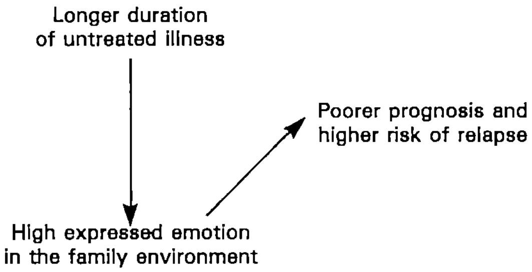

FIG. 3. Model III: mediating variable.

Figure 3 presents another model of indirect causation – one which we consider particularly appealing. This model views EE as an intermediate causal factor – a reaction to the stress of untreated illness in a relative, and a stressor that itself has malignant prognostic implications. Here too, controlling the duration variables would lead to a non-significant association between EE and outcome.

Macmillan *et al*'s interpretation of their data is very likely to be taken as discounting EE as a causal variable, particularly since their discussion firmly discounts EE as a determinant of relapse:

> Although the findings of the present study are not decisive, we regard them as casting considerable doubt on recent speculations that important predictors of outcome are present in the family environment. If such factors exist, it is not clear why they should not have been more apparent in the present relatively homogeneous and well-documented population of patients with early schizophrenia.

It should be clear from Figs 1–3 that causal interpretations of partial associations derive from causal models, not from the statistics themselves. Macmillan *et al* acknowledge that there is no basis for clear specification of a model at this time:

> There is a significant association between longer duration of illness prior to admission and higher CC, the causal sequence of which is unclear.

Psycho-social and pharmacological effects

> Neither of the two components of the CFI emerged as important determinants of relapse/readmission . . . while duration of illness and neuroleptic treatment after discharge are related to relapse (Crow *et al*, 1986). (Macmillan *et al*, 1986*b*).

This statement may appeal to biologically orientated readers, but it is misleading. Their study of EE and outcome was based on a subsample of cases from the larger neuroleptic trial reported by Crow *et al* (1986). When Macmillan *et al* state that the CFI was not a determinant of relapse, they are (mis)interpreting the results of a multivariate survival model, based on their reduced EE subsample. In stating that duration and neuroleptics were "related to relapse", they allude to data from a different sample of cases and to an analysis that did not include EE.

They state that a "crude examination of the percentage relapse/readmission rates in the present study reveals results apparently discrepant with earlier work", and that "we regard them [the findings] as casting considerable doubt on recent speculations that important predictors of outcome are present in the family environment". We disagree.

In Table I the parenthesised figures show both the lowest and highest possible relapse rates within each cell: in every case, the lowest relapse estimate in the high-EE groups is higher than the highest relapse estimate in the low-EE groups. The most *conservative* estimate, taking the lowest possible figure from the high-EE groups and the highest possible figure from the low-EE groups, yields differences of 17%, 18%, and 18% respectively across the three treatment conditions; estimates which exclude the five cases lost to follow-up are considerably higher.

In fact, in these authors' subsample, EE is a *better* predictor of outcome than active neuroleptic treatment within the clinical trial. In our Table I, the difference in relapse rates (excluding dropouts) attributable to EE is roughly 30%, regardless of treatment group; on the other hand, relapse rates for placebo and active treatments in this subsample of cases were not meaningfully different. If there is a medication effect in this table, it is entirely due to the low relapse rates in standard treatment, but this is most likely an artifact, because the criterion for relapse in that group was limited to readmission.

Credibility gap

There are at least two significant errors in Macmillan *et al*'s Table IV and Fig. 1. The first is the reversal of the relapse/no-relapse rates for the low-EE active/standard-treatment conditions in Fig. 1. The table shows the relapse rate as 63% and the no-relapse rate as 31%, but in fact, the correct rates are 31% relapsed and 63% not relapsed, as indicated by the numbers in Table IV. This may be a simple typographical mistake, but it is highly misleading, and it happens to be consistent with the authors' conclusions.

More subtle but equally important is the fact that the numbers in Fig. 1 and Table IV are not consistent, and cannot be correct. In this case, we do not believe the error is likely to be typographical, since all of the marginal statistics in Table IV and Fig. 1 agree.

Table IV shows that six high-EE active-treatment patients relapsed. Since none of the active-treatment patients with high social contact (SC) relapsed (Table IV), all of these six must have been in the high-EE low-SC active-treatment group. The total number of high-EE low-SC patients who relapsed in combined active and standard treatment is reported as 11 in Fig. 1. Since six of these were in the active-treatment group, the remaining five relapsers must have been in the high-EE low-SC standard-treatment group. However, Table IV shows that the total number of low-SC standard-treatment group relapses is only four. Since all the marginals agree, this error must affect more than one cell, to an unknown degree.

Studies of treatment of EE

Studies of the value of treatment of EE in families have obvious bearing on the causal interpretation of the EE–relapse association. If EE is simply a reaction to the behaviour of patients, with no causal importance, it is not clear why reducing it should improve prognosis unless the treatment is also reducing forms of behaviour that are causally relevant. In their discussion, the authors state that "we do not wish to suggest that support and counselling [for families] are not worthwhile . . . but their role in determining outcome has yet to be demonstrated". They thereby ignore a substantial number of controlled clinical trials that have evaluated the efficacy of family intervention programmes which, in conjunction with medication, have been found to significantly reduce relapse rates compared with control conditions (Goldstein, *et al*, 1978; Leff *et al*, 1982; Falloon *et al*, 1985; Hogarty *et al*, 1986).

Is EE relevant to enough schizophrenics?

The authors state that study of EE is not likely to be clinically productive, because relatively few patients (about 30%) return to live with families. Thus, the typical small total *n* in most clinical studies can reach vanishing point in some cells, if one attempts to cross-tabulate EE with other relevant variables, such as amount of contact with high-EE relatives.

Adequacy of sample size to analyse complex multivariate models is a pandemic problem for clinical research: it is certainly not unique to EE, and is no reason to dismiss an important correlate of outcome of schizophrenia. In any event, it is not at all clear that the EE effect is limited to a few unpopulated cells of a complex multivariate model. In fact, the current study found a significant main effect for EE on relapse.

It should be noted that Macmillan *et al* restricted their sample in two significant ways: firstly, they included only patients who had lived with families for three months prior to admission; secondly, they excluded all families who were not fluent in English. Recent research on EE has used a less stringent criterion of frequency of contact – one month out of the three preceding admission (Vaughn *et al*, 1984; Nuechterlein *et al*, 1986). The exclusion of non-English-speaking families may have been logistically convenient, but hardly bears on the relevance of the *concept* of EE for schizophrenic relapse. In fact, there is a recent replication of the basic EE-relapse association with Spanish-speaking families (Jenkins *et al*, 1986). Macmillan *et al*'s experience in England may be that relatively few patients return to family environments, but we must caution against ethnocentric interpretations. In other cultural settings (Jenkins *et al*, 1986), return to a familial setting may in fact be the norm.

Furthermore, it is important that EE may also be a significant prognostic factor outside the family environment. A basic notion underlying EE research is that interpersonal stress may be an important determinant of relapse: although EE has not yet been the focus of detailed empirical study outside the family setting, this would seem to be a reasonable and important extension of existing research. Study of important prognostic factors may ultimately lead to better understanding of the process of relapse, even if initial study must be confined to a select and hard-to-find group of patients.

Methodological details on EE assessment

Macmillan *et al* interviewed only the relative with whom the patient had the most contact, and this is not typical research procedure in EE studies. Usually, relatives with whom the patient has significant contact (Nuechterlein *et al*, 1986; Jenkins *et al*, 1986) are interviewed. Obviously, the more relatives interviewed, the more likely it is that a family will be classified as high in EE (Kottgen *et al*, 1984). Thus, Macmillan *et al* are likely to have under-identified high-EE homes to some degree.

EE and disturbed behaviour ratings (DBR)

Macmillan *et al* state that "the data are consistent with a model of partial independence . . . with DBR unassociated with either CC [critical comments] or SC [social contact]." However, we reanalysed the data in their Table III in several ways. Firstly, we dichotomised DBR at the median (0–2 versus 3 or more), and analysed the matrix with a log–linear procedure (BMDP4F): the analysis yielded a significant effect for EE ($\chi^2=6.07$, $P<0.014$), and a borderline significant interaction between EE and SC ($\chi^2=3.20$, $P<0.074$). Because the interaction term was of borderline significance, the data were reanalysed separately for groups with high and low social contact: these analyses yielded significant results in the high-SC group ($\chi^2=4.25$, $P<0.007$), but there was no significant EE effect in the low-SC group. Dichotomising at 0–1 versus 2 or more also yielded an EE × SC interaction of borderline significance ($\chi^2=3.1$, $P<0.08$), and a significant χ^2 for EE in the high-SC group ($\chi^2=4.02$, $P<0.045$).

The data were also reanalysed using a 2×2 factorial ANOVA. Since the original Table III pooled DBR scores above 3, cases above 3 were assigned a score of 3. Our Table II shows the means: the ANOVA yielded a significant main effect for EE ($F=6.88$; d.f. = 1, 77; $P<0.011$), and an EE × SC interaction of borderline significance ($F=3.68$; d.f. = 1, 77; $P<0.059$).

TABLE II
Disturbed Behaviour Rating (DBR) score by EE and social contact

	Social contact	
	High	*Low*
EE high	2.6	1.7
EE low	1.3	1.5

Furthermore, a Tukey (HSD) test revealed a statistically significant effect of EE for the high-SC group. In short, our analyses are entirely consistent, and demonstrate a significant association between EE and DBR for patients with high SC.

The strategic decision by Macmillan *et al* to dichotomise with a cut-off at 1 is thus quite questionable, and it is difficult to understand the authors' statement that "in the first analysis (DBR dichotomised) the main effect of this variable could also be eliminated . . .". How could this be so with marginals of 12 (DBR = 0) versus 69 (DBR = 1 or more)? In fact, it is not so. When we used that cut-off point, we obtained a χ^2 of 44.33 ($P<0.0001$) for the DBR main effect.

The importance of this reanalysis is that the relationship found here between DBR and EE is consistent with the novel finding that duration of illness prior to admission was related to EE. The relationship between DBR and EE is striking, since the authors took care to "avoid contamination with the factor of duration of symptoms before admission" by devising a "revised form of rating . . . in which the temporal element was removed". This association may simply be a peculiarity of their sample, since prior research has uniformly failed to find a relationship between EE and level of behavioural disturbance.

On the other hand, the possibility remains that Macmillan *et al* have uncovered a new and potentially important set of relationships of EE and the attributes of patients (duration and disturbed behaviour prior to initial treatment). In fact, currently, we are actively pursuing some of the leads suggested by their report in another sample of first-break cases.

Closing comment

It is unfortunate that Macmillan *et al* chose to present their research on the prognostic importance of psychosocial factors in a manner that implies that such research in the area of schizophrenic outcome somehow conflicts with research on pharmacological treatment. In fact, there is growing interest in the integration of these two areas of study.

> If genuine determinants of poor outcome are present in the immediate families of patients with schizophrenia, they are somewhat elusive and when present, their effects are unlikely to be large. The search for such influences should not detract from the much better documented, although limited prophylactic effects of neuroleptic medication. (Macmillan *et al*, 1986*a*)

We are certainly not suggesting that further research on neuroleptics is not needed. What we are suggesting is that premature closure on *any* research area, particularly a variable with such strong research credentials as EE, would be unfortunate for the advance of knowledge of the determinants of outcome in schizophrenia.

Expressed Emotion and Relapse in First Episodes of Schizophrenia

J. F. MACMILLAN, T. J. CROW, A. L. JOHNSON and E. C. JOHNSTONE

In the preceding paper, Mintz *et al* have raised a number of criticisms and points relating to our study, to which we are pleased to respond.

Their rejoinder is headed by two quotations from our paper which are described as presenting the reader with a "difficult contradiction". The first quotation reports a statistically significant ($P = 0.036$) association between the level of critical comments and relapse, while the second states that this component of the Camberwell Family Interview was not a determinant of relapse at the 5% level. The first quotation refers to a direct (unadjusted) comparison of relapse rates in the groups with low and high levels of critical comments (CC), while the second refers to the same comparison adjusted for two prognostic factors, treatment and duration of illness. There is therefore no contradiction between the statements.

The single association between critical comments and relapse that reached 'generally accepted levels of statistical significance' was unadjusted for two prognostic factors. The prognostic importance of these factors had been indicated by our previous analysis (Crow *et al*, 1986). These factors were not identified by statistically significant tests carried out in the sample of patients rated for expressed emotion (see Altman, 1985). Obviously there could be other confounding effects produced by other variables which we have not assessed.

Adjustment of the CC comparison by treatment is not only justified but necessary since some patients received placebo and a difference in outcome between treatment groups *is expected*. Similarly, it is logical to adjust the CC comparison by a measure of severity of illness; such adjustment is a common feature of epidemiological studies of disease progression.

Amalgamation of the 'active' and 'standard' treatment groups is of course not necessary. When the data are analysed with patients stratified into three treatment groups (active, placebo and standard), results are essentially similar to those presented in our paper; comparison of relapse rates in the two CC groups adjusted for treatment and the period between onset and admission gives $\chi^2 = 2.16$, d.f. $= 1$, $P = 0.14$. If the comparison of the two CC groups is adjusted *only* for treatment the statistical significance of the unadjusted comparison also 'disappears' whether active and standard treatment are combined ($\chi^2=2.84$, d.f. = 1, $P=0.092$) or not ($\chi^2=3.34$, d.f. = 1, $P=0.068$). Therefore neither pooling the findings in our active and standard treatment groups nor adjustment for duration of illness is necessary for us to conclude that critical comments do not significantly predict outcome. The effect of high CC estimated from the Cox model including treatment *only* gives a hazard rate ratio of 1.88 (with 95% confidence limits at 0.97 and 3.64). Ignoring the confounding effect of treatment would be inconsistent with the results of our study, and inconsistent with a very large body of research upon the effect of neuroleptic prophylaxis in schizophrenia (Davis, 1975).

None of these comparisons yield a significant effect for CC, and it should be noted that the different definitions of relapse do not invalidate our analysis. In these survival models, stratification allows the assumption of a multiplicative effect for EE without any assumption about the form of the hazard for relapse. Indeed this hazard may be quite different in the separate strata. With only 40 relapses in 77 patients we do not have a sensitive test of the assumption of a constant multiplicative effect for EE.

EE and treatment

Mintz *et al* suggest that our Table IV provides sufficient data for an analysis of crude 2-year relapse rates. This is not correct. Patients entered in our study were followed from hospital discharge to relapse/readmission, loss to follow-up, or to 1 August 1982 (up to a maximum of 2 years). Thus patients entered after 1 August 1980 were followed up for less than 2 years; since recruitment did not terminate until February 1982, some were followed for considerably less. Further, the presentation by Mintz *et al* provides no estimate of the variation in relapse rates. Table I shows actuarial percentage relapse-free rates (and 95% confidence limits) at one year from discharge.

TABLE I

Actuarial percentages (and 95% confidence limits) relapse-free at one year from hospital discharge

		Treatment group	
	Active	*Standard*	*Placebo*
Low EE	63 (36, 89)	91 (73, 100)	38 (6, 69)
High EE	43 (6, 80)	63 (36, 89)	33 (11, 55)

We chose this interval because the number of patients at risk after one year in each subgroup was very small. Simply taking differences between the percentages in Table I of Mintz *et al* fails to take account of sampling variation; the 95% confidence limits in our Table I show that the variation is large.

Mintz *et al* have drawn attention to errors in our Fig. 1. It should be as shown here.

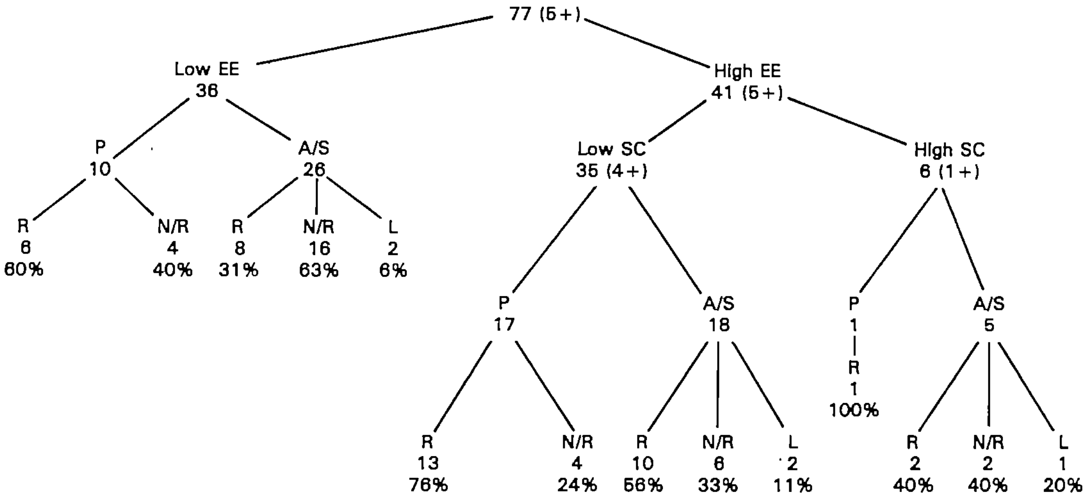

FIG. 1 Branching diagram of relapse rates in patients divided by expressed emotion and allocation of medication. EE = expressed emotion, SC = social contact, P = placebo medication, A/S = active or standard medication, R = relapsed, N/R = not relapsed at conclusion of study, L = lost to contact. Numbers represent individual cases; those in brackets refer to patients not discharged from hospital.

EE and duration of untreated illness

Mintz *et al* propose three models of interaction between level of critical comments, duration of onset and time of relapse. We make no comment, as the estimates of the effect of high relative to low critical comments on relapse rates are similar whether adjusted for treatment alone or for both treatment and duration of illness, being non-significant at the 5% level and having wide 95% confidence limits.

Studies of treatment of EE

There is a well recognised bias in favour of publishing positive results especially in clinical trials (Begg, 1985), and the majority of studies of expressed emotion have incorporated only small samples of patients.

The most recent, and by far the largest of the studies referred to (Hogarty *et al*, 1986) illustrates some of the limitations of current knowledge. In discussing their findings, Hogarty *et al* note that 'causal' inferences regarding EE and relapse need to be qualified:

> It is possible that the high EE status of households with a relapsed patient is due to the relapse event itself . . . it is as possible to argue that some families changed their EE status because the patient's condition improved as it is to suggest that lowered EE 'caused' a better patient outcome.

These authors continue:

> we wish to emphasise that these early prophylactic effects are more likely related to the *delay* of schizophrenic relapse than to its prevention. . . . Although a main effect of family treatment is being sustained, and much of the relapse is associated with drug non-compliance, we are clearly not preventing schizophrenic relapse. Recently Leff *et al.* (1985) reported the first two-year follow-up of a nine-month controlled family study and argued that only one (14%) of the seven family therapy patients relapsed when EE on 'face to face contact' had been reduced, compared with 78% relapse among drug treated controls. However, when one examines the outcome of their original sample of 12 experimental and 12 control patients, 75% of controls indeed relapsed (seven of these while receiving medication), but 50% of experimental patients also had a poor outcome: two relapsed while receiving drug, two relapsed while not receiving medication and two committed suicide.

Hogarty *et al* also note that "only Falloon *et al* described a second year outcome of family intervention significantly better than what one would exponentially predict for drug-maintained patients", and go on to discuss the apparently high rates of relapse in the drug-treated controls in these studies:

> nine-month relapse rates with maintenance chemotherapy alone exceed the 12-month 41% relapse rate of our own trial and the characteristic 12-month rate among published, drug-controlled maintenance studies. . . . As such, relapse rates among our own controls either reflects a prophylactic effect of our 'active' control treatment . . . or indicates that drug controls in the contrasting studies (i.e. those of Goldstein *et al.* 1978, Leff *et al.* 1985, Falloon *et al.* 1982 and Köttgen *et al.* 1984) might contain covert drug defaulters.

Perusal of Hogarty *et al*'s frank and critical discussion indicates that this literature is at an early stage. We doubt whether there is as yet a body of research which is sufficiently rigorous to convince a sceptical observer (or to justify the use of one-tailed significance tests).

Is EE relevant to enough schizophrenics?

Mintz *et al* have misinterpreted our remarks about the relevance of expressed emotion to schizophrenic patients. We reiterate that despite our efforts, this assessment could be performed in only one-third of our total sample, and the combination of high critical comments and high social contact was very uncommon (7 out of an original sample of 253 patients). We do not feel in a position to comment about the effects of expressed emotion outside the family environment. We do not consider our sample particularly ethnocentric except that the population was drawn from within and around North West Thames Region (a metropolitan area which contains a spectrum of social classes and some recent immigrant groups).

EE and Disturbed Behaviour Ratings

We were interested in the reanalysis of the relationships between EE and Disturbed Behaviour Rating (DBR), although Mintz *et al* have misunderstood our presentation. We did not dichotomise DBR below 1, but above 1, as stated clearly in our paper. The appropriate marginals are 39 (DBR = 1) and 42 (DBR = 2), and so the elimination of the main effect of DBR is fully justified. Dichotomising DBR as 2 or less versus 3 or more gives marginals of 58 and 23 respectively, and is not consistent with dichotomising at the median.

We have followed through the suggestion of Mintz *et al* to analyse the DBR scores by analysis of variance. Some care is necessary because the DBR scores are not distributed symmetrically. The means presented in their Table II are not sensible summary statistics for these data which have a pooled standard deviation of 1.0. Using the methods described by Snedecor & Cochran (1967) for the analysis of unbalanced data in a 2 × 2 factorial design, we have first repeated the analysis reported by Mintz *et al*, but with somewhat different results; in our analysis we find a non-significant main effect of CC ($F=3.80$; d.f. = 1, 77; $0.05<P<0.10$) and non-significant interaction ($F=3.68$; d.f. = 1, 77; $0.05<P<0.10$). Secondly, we have used actual DBR scores (without recoding scores of 4 and 5 to 3), but have transformed them by adding one and taking square roots, yielding stable subgroup variances and a symmetrical distribution of scores. Here there is a significant main effect for CC ($F=4.52$; d.f. = 1, 77; $0.025<P<0.05$), but not for social contact (SC) ($F=1.88$; d.f. = 1, 77; $0.10<P<0.20$) or their interaction ($F=3.52$; d.f. = 1, 77; $0.05<P<0.10$). The actual DBR scores as well as back-transformed means and 95% confidence limits are presented in Table II.

TABLE II

Distribution of DBR scores by critical comments and social contact

DBR scores	*Social contact <35 hours*		*Social contact >35 hours*	
	CC<6	*CC>6*	*CC<6*	*CC>6*
0	4	5	3	–
1	6	14	6	1
2	6	8	4	1
3	4	9	–	2
4	–	2	2	3
5	–	1	–	–
Mean*	1.4	1.7	1.3	2.9
(95% CL)*	(0.9, 1.9)	(1.3, 2.1)	(0.8, 1.9)	(1.9, 4.1)

*Back-transformed after using $\sqrt{(x+1)}$ transformation.

Therefore there appears to be a relationship between critical comments and disturbed behaviour, but it is less clear-cut than Mintz *et al*'s analysis suggests.

In conclusion

Notwithstanding the points that Mintz *et al* have raised, we consider our findings cast doubt on the generality of the relationship between expressed emotion and relapse: in our sample of first-episode schizophrenic patients, no feature of the Camberwell Family Interview emerged as an important predictor. Obviously more research is required. Progress will be made when findings can be replicated by both sceptics and believers.

The Phenomenology of Acute Organic Psychosis

Comparison with Acute Schizophrenia

J. CUTTING

The psychopathology of acute organic psychosis was investigated by interviewing 74 patients using the Present State Examination (PSE). Their delusions, perceptual disturbance, thought disorder, and emotional disorder were categorised and then compared with those seen in 74 acute schizophrenics. In acute organic psychosis there was a particular pattern to the delusions, perceptual disturbance, and thought disorder, which was quite unlike that seen in acute schizophrenia. These results have implications for theories claiming that schizophrenia is an organic psychosis. It is suggested that the psychopathology in acute organic psychosis has very different origins from that seen in schizophrenia.

Over the past decade, several convincing pieces of evidence have emerged to suggest an organic cause for schizophrenia. Chief among these are the facts that schizophrenics have an unusually high rate of perinatal complications (Reveley *et al*, 1984), that they tend to have been born in the winter months when viral infections are rife (Hare & Walter, 1978), and that a minority have ventricular enlargement on CT scan (Johnstone *et al*, 1976).

Facts such as these have meant that the psychogenic and social formulations of the 1950s and 1960s have given way to a more committed organic position, illustrated by the title of a recent American book, *Schizophrenia as a Brain Disease* (Henn & Nasrallah, 1982). In the 1950s and 1960s, an organic cause for schizophrenia was so disputed that psychoses with phenomena similar to those of typical schizophrenia arising in epileptics (Slater *et al*, 1963) or in those with endocrine disease (Bleuler, 1951) had to be labelled as schizophreniform psychoses: now, the situation is reversed, and certain organic psychoses, particularly those occurring with temporal lobe damage, are regarded by some psychiatrists (e.g. Flor-Henry, 1983) as a model for typical schizophrenia itself.

What is forgotten in this resurgence of interest in the organic basis of schizophrenia is the fact that those psychiatrists who first described the condition were at pains to stress the *fundamental differences* between schizophrenia and all known organic conditions. Bleuler (1911) wrote:

> In schizophrenia, even when well-advanced, all the simple mental functions, as far as we know, are intact. In particular, memory, unlike what happens in true dementia, is unaffected . . . One may find to one's surprise that under an apparent envelope of dementia, intelligence is much less affected than one might imagine, as if it were only asleep.

Jaspers (1913) commented:

> We may note the profound psychopathological difference between, for example, general paralysis and schizophrenia, between the crude organic *destruction* – machinery smashed up – and the *distraction* of mind.

The purpose of this paper is not to undermine the organic claims concerning the cause of schizophrenia, but to show that the clinical picture of schizophrenia is not the same as that of a symptomatic psychosis. Therefore, if there is a biological basis for schizophrenia, it cannot be the same as that underlying the usual symptomatic psychoses in which an essentially similar mental state may be produced by very diverse physical conditions. The aim is to show that, although delusions, hallucinations, emotional disturbance and formal thought disorder are common to both organic psychosis and schizophrenia, the patterns in the two cases are quite different. It might be considered naïve to point out such differences, when the distinction between 'functional' and 'organic' phenomena is so well known. However, the recent blurring of the functional–organic distinction, as outlined above, makes it worthwhile to re-examine the classic phenomena of an organic psychosis. The point at issue is whether differences from schizophrenia are as great as traditional teaching would have us believe, or as little as some contemporary psychiatrists are now suggesting.

The traditional view of a uniform pattern to the clinical presentation of an acute organic psychosis despite a multitude of causes, as well as its distinction from functional psychosis, can be attributed to the writings of Bonhoeffer (1909). He wrote:

> Crude exogenous organic damage of the most varying kind can produce acute psychotic clinical pictures of a basically uniform kind.

The detailed study by Wolff & Curran (1935) supported this view, and more recently Lipowski (1980) has suggested a physiological mechanism, involving arousal and sleep, which explains how different physical conditions can produce the same clinical picture. In fact the literature on the general phenomenology of acute organic psychosis is rather meagre, most work on the subject being reports of yet another physical condition or drug which can cause the clinical syndrome, with little appreciation on the part of the author that they are dealing with a 'uniform' disorder. On the question of the difference between an acute delirious picture and schizophrenia, the different course and the frequent EEG abnormalities in the former are undoubtedly powerful aids in differential diagnosis. It is the clinical differences or similarities, however, which are the focus of this paper. To quote Bonhoeffer again, it is the following statement of his which is to be examined:

> It is clear that a complete distinction between the symptomatology of the exogenous clinical pictures and that of the psychoses which we regard as endogenous cannot be maintained.

Method

Patients

Organic psychotics

The general characteristics, physical state and cognitive impairment of the 74 patients included in the present study have already been reported (Cutting, 1980). In that paper, however, only brief mention was made of their psychopathology, and it is this issue which is examined here.

They were consecutive psychiatric referrals from the general wards of two London teaching hospitals, who fulfilled the following criteria: they had to be psychotic (delusions, gross perceptual disturbance or marked thought disorder), and the psychosis had to be secondary to some clearly identifiable organic cause. Of the 100 psychotic patients seen, 26 had to be excluded, 16 because the psychosis had antedated the physical condition for which they were admitted, and 10 because the psychosis could equally well have been psychogenic or psychosocial in cause, there being no real evidence of cerebral dysfunction. This left 74 clear-cut cases of acute organic psychosis, none of whom had been psychotic before they developed their physical condition.

Each patient was interviewed using the Present State Examination (PSE; Wing *et al*, 1974), and was given a short battery of cognitive tests: four subtests of the Wechsler Memory Scale, comprising orientation, general information, forward digit span and paired-associate learning.

The mean age of the patients was 57.4 years and the sex ratio was exactly equal.

Acute schizophrenics

The controls were 74 acute schizophrenics (Research Diagnostic Criteria (RDC): Spitzer *et al* (1975)). They had all been seen personally and interviewed using either the PSE or the SADS (Schedule for Affective Disorders and Schizophrenia: Spitzer & Endicott (1978)). The change in the interviewing instrument is not of much consequence because many of the psychotic items in the SADS are identical to or derived from PSE items. For the present study, those patients interviewed with the SADS were reassigned PSE symptoms to make the comparison with organic psychotics possible. The schizophrenics were in-patients in an acute admission ward, and had been interviewed as part of a variety of research projects over the years. For the purpose of comparison with first-episode acute organic psychotics, as many as possible of the 74 schizophrenics chosen were also in their first episode. Due to the relative rarity of such cases, the 62 patients in their first-ever episode were complemented with 12 patients in a second discrete episode. The mean age of the schizophrenics was 27.1; there were 41 males and 33 females.

Procedure

Delusions

The organic patients' delusions were analysed with three main aims: (a) to see if they met the phenomenological criteria for schizophrenia according to the RDC (Spitzer *et al*, 1975) or Catego schemes (Wing *et al*, 1974); (b) to examine the validity of a recently suggested classification of organic delusions (Cummings, 1985) into 'simple persecutory', 'complex persecutory', 'hypomanic' and 'those associated with specific neurological defects'; and (c) to search for specific characteristics.

The schizophrenics with delusions were grouped in a way which allowed the best comparison with organic patients. Four groups were distinguished: those with only first-rank symptom delusions (thought interference, passivity, control, delusional perception) or whose persecutory delusions stemmed from these; those with other non-persecutory delusions only; those with both the above types; and those with only persecutory delusions, who fulfilled other criteria for schizophrenia. The first group were typical Catego schizophrenics, the second group were typical RDC schizophrenics and the third group were typical of both.

TABLE I
Simple persecutory delusions in organic patients

Case	*Sex*	*Age*	*Cause*	*Content of delusion*
1	M	49	Alcohol	Doctor had gun to kill him
2	M	60	Respiratory failure	Someone slipped something in drink to cause him trouble with police
3	F	51	Carcinoma	Husband conspiring against her
4	F	47	Alcohol	Evil eye about; nurses not treating her right
5	M	41	Liver failure	He was being experimented upon
6	F	79	Myxoedema	Nurses poisoning her
7	M	63	Carcinoma	People conspiring to frighten him
8	M	73	Right parietal CVA	Nurses trying to kill him

TABLE II
Mood-congruent delusions in organic patients

Case	*Sex*	*Age*	*Cause*	*Content of delusion*
9	M	64	Carcinoma	Director of Wimpey was his friend; he was filthy; doctors going to kill him
10	M	77	Drugs	He was an 'honourable'; his grandfather was Duke of Bedford; he had royal blood in his veins
11	F	88	Drugs	She was a nuisance; nurses opened her letters; stains on curtains meant she was sick; kicked in mouth
12	F	52	Renal failure	She was a nuisance; patients nearby thought she was getting too much attention; she didn't take tablets
13	F	80	Cardiac failure	She was not paying her way; pension-book not kept up to date
14	M	57	Respiratory failure	He had insulted doctors; doctors were in league with saboteurs
15	F	56	Drugs	She was accused of something wrong (e.g. tearing up box of tissues); porters jeering; she was being given wrong pills
16	M	63	Alcohol	He was on blasphemy charge for masturbating into cider and drinking it; he had defrauded Social Security
17	F	49	SLE	Someone accusing her of walking barefoot; doctors trying to poison her with arsenic in chips

Perceptual disturbance

The modality (visual, auditory etc.), form (hallucination, illusion, distortion, first person, second person) and content (verbal, non-verbal, animal, human etc.) were all analysed to test the traditional view that organic perceptual disturbance is characteristically visual rather than auditory, illusion and distortion rather than hallucination, and non-verbal rather than verbal.

Thought disorder

Any disorder of thinking other than delusion was categorised using the nine headings in the PSE: slowness, pressure, non-social speech, muteness, restricted quantity, neologisms, incoherence, flight of ideas and poverty of content. These proved inadequate for both groups of patients and a further categorisation using Andreasen's (1979) scale of Thought, Language and Communication disorders (TLC) was carried out on the protocols, as it was published after the data had been collected.

Emotional disturbance

The predominant observed emotional disturbance was noted, and was recorded as one of the ten PSE categories: anxious, depressed, histrionic, hypomanic, hostile and irritable, suspicious, perplexed, labile, blunted and incongruous. (Lability was regarded as the presence in the course of the interview of at least three of these.)

Results

Delusions

The organic patients' delusions are summarised in Tables I–III. Thirty-five of the 74 patients had delusions. Cummings' scheme, with some alterations, was helpful in

TABLE III
Complex, bizarre or multiple delusions in organic patients

Case	*Sex*	*Age*	*Cause*	*Content of delusion*
18	F	70	Right parietal CVA	When people washed in sink they scrubbed her back; things shown to her became muddled up in pillow; carrot in windpipe
19	F	69	Drugs	Thoughts controlled; something funny going on; she was dying; woman in next bed being harmed
20	M	58	Cardiac failure	Irish Catholics from Streatham driving to Brixton and harming locals by transmitting decomposed matter into their and his own necks by affecting circulatory system parallel to bloodstream called 'man's money'
21	M	76	Respiratory failure	Wife had left him
22	M	59	Drugs	X-ray girls involved in sexual misdemeanours; wife outside curtain; something in head turning to dust
23	F	40	Carcinoma	Mother, sister and herself dying; relatives in ward; nurses going to kill her
24	F	76	Myxoedema	Relatives and herself had died; doctor on ward going to marry a beautiful person
25	F	69	Electrolyte imbalance	Husband eaten by cannibal; drunken nurses obtaining money from patients by doing unspeakable things; she had VD
26	F	48	Electrolyte imbalance	Fire in hospital; children coming to Casualty choking; husband and friend underneath bed, moving it; psychologist testing her
27	M	68	Carcinoma	Unpleasant incidents on ward blamed on him; all the excrement in ward is his; hospital floating on water; daughter to be shot
28	F	37	Alcohol	Doctor taking blood out of her and putting it back into neck; brother out to kill her, her dog and old ladies
29	M	81	Respiratory failure	People exporting illicit material, giving dummy drugs; he was substitute patient for someone else
30	M	62	Cardiac failure	About to die; nurses moving things around in bags, possibly dynamite, and involving IRA; doctors not real doctors
31	M	27	Epilepsy	About to die; people changing things to test him; discrepancy between his thoughts and what he expected to think
32	F	28	SLE	Something bad going to happen; mother dying
33	M	63	Cardiac failure	Building bombarded; police all around
34	F	57	Drugs	Son down road taking drugs; men out to kill husband
35	F	37	Carcinoma	Baby taken away; nurses met daily to decide who was worst patient on the ward

providing a framework for classification. Eight patients had simple persecutory delusions alone (Table I). Nine had predominantly *mood-congruent delusions* (Table II). This replaces Cummings' term 'hypomanic delusions', as only one patient had delusions congruent with elation, whereas one had a mixed affective picture, and seven had depressive delusions. The remaining 18 deluded patients had complex, multiple or bizarre delusions, the nature of which were inadequately conveyed by Cummings' term 'complex persecutory delusions'. Table III shows that they were neither mood-congruent (although a depressive content was often present) nor predominantly persecutory (although this component was often part of the picture). One patient (case 18), with a right parietal lesion, believed that objects in front of her were physically enmeshed with her body and bed, a belief which probably derived from the sort of perceptual distortions described by Critchley (1953) in patients with parietal damage. For this reason it was placed in Cummings' category of 'delusions associated with specific neurological defects'. (His cases within this category – cortical blindness and its denial, aphasia and its denial, reduplicative paramnesia – are, in fact, better regarded as 'delusions based on a specific neuropsychological deficit', as many deluded and non-deluded people might have an associated neurological lesion without this constituting a cause.)

If Cummings' term inadequately represents the delusions in Table III, is there any better way of characterising them? Only two deluded patients could be regarded as showing first-rank symptoms (cases 19 and 20), compared with 56 of the 67 deluded schizophrenics (Table IV), and in the first

TABLE IV

Grouping of deluded schizophrenics and organic patients

Group	*Schizophrenia (number of patients)*	*Organic psychosis (number of patients)*
1. First-rank symptom delusions only (thought intrusion, broadcasting, withdrawal, echo; control, alien penetration; primary), with or without persecutory delusions	37	0
2. First-rank symptom delusions with non-persecutory delusions	19	2
3. Non-persecutory delusions without first-rank symptom delusions	10	16
4. Persecutory delusions only	1	8
5. Mood-congruent delusions only	0	9
6. No delusions	7	39
	74	74

TABLE V

Delusional themes in 29 schizophrenics with non-first-rank-symptom delusions

1. Night club singer in love with him
2. Passing on classified secrets
3. Going to have eight babies; father died and came to life
4. Brain rotating; other people wearing her clothes
5. Time altered and everything had happened before
6. Pregnant
7. Sister measuring doctor's pulse on landing below
8. Son of God; brother on same aeroplane; blood sucked out
9. Turned into a dog; world ending; she and others dying
10. Turned into different person
11. Back broken
12. Body would wash away if he had shower
13. Mother died by falling off donkey
14. Vagina burnt
15. Half Chinese and 10% woman
16. Going to die in 100 days
17. Had different name
18. Everything added up to 20
19. Parents not his real parents
20. Right side of body empty; personality shifted to left shoulder
21. Russians invading South London and affecting weather
22. Second coming about to occur; testicles going to be cut off
23. Throat cut; going to die; boyfriend would be harmed if she said something
24. Dying; being turned into a man; bleeding to death
25. Wife being impersonated on phone and wired up; head blown up
26. Christ
27. Throat diseased
28. Died several times in past
29. Things which happened in past (e.g. kissing in 1967) meant rain in 1982

of these there was marked clouding of consciousness, so only one patient out of the entire 35 can be regarded as a Catego nuclear schizophrenic (S+ in Wing *et al*'s scheme). And even though 15 had bizarre or multiple delusions, one of the criteria for probable schizophrenia in the RDC scheme, in only six of these did the delusions last 2 weeks, another necessary criterion.

Two characteristic themes can be discerned, however, in the organically induced delusions in Table III. These can be described as a belief in *imminent misadventure to others* and a belief in *bizarre happenings in the immediate vicinity*. Fear of misadventure to others was evident in 12 organic cases, and bizarre goings-on in the immediate vicinity in 10 organic cases. The particular link with organic psychosis is emphasised if one inspects Table V, which summarises the themes of the schizophrenics' non-first-rank-symptom delusions. Only six of the 67 deluded schizophrenics had comparable themes: something going to happen to boyfriend if she said something (case 23), nursing sister at top of stairs measuring pulse of doctor in ward below (case 7), she and others were dying as world was ending (case 9), mother had died by falling off a donkey into the sea (case 13), father had died and then returned to life (case 3) and wife was being impersonated and wired up (case 25). The most significant discriminator between organic and schizophrenic delusional themes appeared to be whether others were the *victims or principal characters* in an unfolding drama as opposed to *agents perpetrating some action against the self*. In 15 of the 35 deluded organic patients the self was *not* the principal target or centre of the drama, whereas this was true in only six of 67 deluded schizophrenics ($\chi^2 = 16.2$, $P < 0.01$). One cannot simply argue that the organic delusions were mere misinterpretations of real events in the immediate environment, because most were taking place at a distance (e.g. down the road, in the X-ray department, outside the building, in the locality of Brixton, in Casualty). Indeed, it was the precise spatial location of the events recounted that gave the organic delusions much of their character.

Perceptual disturbance

Of the organic psychotics, 25 had visual hallucinations (people in eleven cases, people and animals in five, animals or insects in six and objects in three). Auditory hallucinations occurred in 13 cases (non-verbal in two (bagpipes, babies crying), own name called out in two, relatives calling out for help in two, snatches of conversation in two (lovers' tiffs, ward gossip), God's voice in one (content of which patient would not divulge), tape-recorder in one (content unknown), voices talking to the patient in one (with whom she was conversing), and voices talking about the patient with an affective content in two ('Jesus Christ he's on a masturbation charge.' 'She'd better come with us otherwise she'll come to harm.'). Three patients had tactile hallucinations (something crawling on her, bed felt wet, bed moving). Three patients had visual distortions (things appeared elevated and as if in a mirror, things appeared to become enmeshed in her bed and body, corner of room looked like a dirty old barn).

In the schizophrenic group, by comparison, 12 patients had visual hallucinations (people in two, animals in one, funeral scene in one, witches in one, words on ticker-tape in one, disembodied parts of body - eye, leg - in two, objects in one and not divulged in three). There were 25 patients with auditory hallucinations, all voices (discussing or commenting or arguing in third person in ten, echoing thoughts in three, telling the patient what to think or do in three, calling name or single words in four and content not divulged in five). Tactile hallucinations occurred in three patients (pressure on eyeball, burning in vagina, blows on back). Visual distortions were present in 25 patients (predominantly in six that colours were vivid, in eleven that objects around them were strange, and in eight that people looked distorted).

One feature that was confined to the organic group was mistaken identification of people: ten of the organic patients either mistook ward staff for close relatives or thought a visiting relative was someone else. None of the schizophrenics did this.

Thought disorder

Formal thought disorder was present in 47 organic patients. (This rating was made independently of the presence of delusions: 18 of these 47 were also deluded, and 17 of the 27 non-thought-disordered were deluded.) Using the PSE items (Table VI), only 20 of these 47 could be categorised. Using Andreasen's scale, however, all 47 could be placed in at least one of her 18 categories, albeit with some difficulty in the case of tangentiality and illogicality.

The largest group was made up of 15 patients whose thinking was illogical to a marked degree. In all cases this emerged during questions about orientation. One woman claimed that it must be 20 May because her sister had died then, without explaining why the date of her sister's death should determine today's date. The remaining 14 gave fantastic or grossly incorrect answers to questions about orientation in place (e.g. East Finchley airport, waiting at a bus-stop, in Wales one minute and in London the next, on a boat) and when asked to justify their statements resorted to evasion (e.g. 'Well, it looks a bit like an airport') or inconsequential remarks (e.g. 'It's a boat because all my friends are here'). Their disorientation could not be attributed entirely to memory or perceptual disorder, because of the bizarre choice of place in some instances (even non-existent, e.g. East Finchley airport) and because in several instances a patient would try to explain a correct perception within the false framework (e.g. one man, who believed he was at home and found himself surrounded by beds, was puzzled why his wife had bought so many beds).

TABLE VI
Formal thought disorder

	Number of patients with marked abnormality[1]	
	Organic patients (n = 74)	*Schizophrenics (n = 74)*
PSE items		
Slowness	14[2]	3
Pressure	2[2]	0
Non-social speech	0	0
Muteness	0	0
Restricted quantity	14[2]	1
Neologisms	2	4
Incoherence	1	3
Flight of ideas	2[2]	0
Poverty of content	1	1
Total PSE items	20	12
TLC items		
Poverty of speech	14	1
Poverty of content of speech	1	1
Pressure of speech	2	0
Distractible speech	2	0
Tangentiality	6[3]	2
Derailment	0	10
Incoherence	1	3
Illogicality	15[4]	0
Clanging	0	0
Neologisms	0	1
Word-approximation	2	0
Circumstantiality	4	1
Loss of goal	0	1
Perseveration	0	0
Echolalia	0	0
Blocking	0	1
Stilted speech	0	2
Self-reference	0	0
Total TLC items	47	23

1. Only predominant feature counted.
2. The two patients with flight of ideas also had pressure, and the 14 with slowness also had restricted quantity.
3. Speech better regarded as irrelevant rather than tangential (see text).
4. Of these, 14 had fantastic disorientation which they justified illogically (see text).

The next largest group - 14 patients - had a combination of apathy, slow speech and restricted or impoverished output. They were not grossly disorientated but complained subjectively of muddled thinking and did poorly on the verbal learning test.

Six patients were categorised as having tangential speech. According to Andreasen (1979), tangentiality is

> replying to a question in an oblique, tangential or even irrelevant manner. The reply may be related to the question in some distant way. Or the reply may be unrelated and seem totally irrelevant.

TABLE VII
Emotional disturbance

	Number of patients with marked disturbance[1]	
	Organic patients	*Schizophrenics*
Anxiety	8	7
Depression	14	10
Histrionics	0	0
Hypomania	10	3
Irritability/hostility	4	1
Suspiciousness	3	2
Perplexity	5	8
Lability	11	3
Blunting	0	1
Inappropriateness	0	6
Total	55	41

1. Only predominant emotion counted.

In the organic patients the replies were irrelevant rather than tangential. For example, one man, when asked where he thought he was, announced that he was allergic to flowers. Another, asked what the matter was, said that he kept seeing 'a hand like a thieving monkey's paw crossing my vision'. Another replied to a simple question on orientation: 'You're nervous of people, I can see it.'

The remaining 12 organic patients with thought disorder had either prominent circumstantiality (giving long rambling accounts), distractibility (interrupting the interview every time there was a noise from a neighbouring bed), word-approximations ('doctoress' for housewoman, 'man's money' (case 20 in Table III)), pressure of speech with flight of ideas, incoherence (mumbled ungrammatical statements) or poverty of content (vacuous answers).

The 23 acute schizophrenics with prominent thought disorder (at least grade 2 on Andreasen's scale) had a different pattern, although numbers were too small for any but three differences to be significant (poverty of speech, $\chi^2=12.5$, $P<0.01$; derailment, $\chi^2=9.8$, $P<0.01$; illogicality, $\chi^2=15.8$, $P<0.01$). In Andreasen's scheme, derailment and tangentiality have the same form, but in the former the abnormality is most obvious in sustained discourse, while the latter refers to oblique or irrelevant replies to questions. Schizophrenics were more likely to offer lengthy explanations of how they felt and thus derailment was more noticeable. In the schizophrenics, in contrast to the organic patients, the link between one statement and another, or question and answer, was usually just discernible, as in the following schizophrenic's answer to my question, 'Do you think you had a breakdown?' 'Yes it's in your. I suppose it's a lack of faith. It's as if you want to arrive at some results and fear things as if improvement. It's just a question of learning.' The organic patients tended to answer some questions quite competently and then intersperse a single irrelevant remark.

Emotional disturbance

There were no marked differences between the two diagnostic groups (Table VII). The organic patients were more likely to be hypomanic ($\chi^2=4.1$, $P<0.05$) or labile ($\chi^2=5.0$, $P<0.05$), and more likely to have an overall emotional disturbance ($\chi^2=13.0$, $P<0.01$).

Discussion

The aim of the study was to reconsider the traditional view that acute schizophrenia and acute organic psychosis are quite distinct phenomenologically. Several authors in recent years have been trying to link these conditions at a biological level, and it might be that phenomenological differences have been exaggerated in the past. The overwhelming conclusion must be that although delusions, hallucinations, formal thought disorder and emotional disorder are common to both, with the exception of the last of these the pattern in each case is quite distinct. A subsidiary aim was to draw attention to the psychopathology of acute organic psychosis itself, a subject which has received little attention in the recent literature. On this point, although the observations were rather impressionistic, it appeared that the delusions, perceptual disturbance and thought disorder had characteristics which made them quite unlike those seen in other psychoses. (The type of hallucinations seen has long been regarded as characteristic, but less is written about the delusions and thought disorder.)

Some methodological problems

Patients with an acute organic psychosis tend to fluctuate in their mental state, even from minute to minute, and a single interview is liable to be unrepresentative of their psychopathology, particularly since they may be amnesic for what they believed, felt or experienced a short while ago. This is likely to be less true in the case of acute schizophrenia, but even here one cannot hope to elicit the entire range of abnormal beliefs in one interview.

In the organic patients it was sometimes difficult to be sure whether a false statement (e.g. my mother is dying) was an autochthonous belief, a mistaken belief through misperceiving another patient for a relative, a true hallucination, or muddled reasoning mediated by a variety of cognitive defects including amnesia and inattention. In many cases, however, the content of the organic delusion either was very bizarre or concerned events outside the patient's immediate environment, so that simple perceptual explanations could be rejected. In any case some schizophrenics' statements are difficult to categorise precisely as perceptual or ideational, and even their delusions, according to some authorities, may originate in an earlier perceptual disturbance (e.g. delusional mood (Conrad, 1958)), so the problem in categorising the organic phenomena is not specific.

The difference in age between the two groups could conceivably account for some of the differences in delusional content; but if one subdivides the organic patients into a younger and older group, the 39 patients aged 58 or older contained four with paranoid, five with mood-congruent and nine with bizarre delusions, and the 35 patients aged 57 or under contained four with paranoid, four with mood-congruent and nine with bizarre delusions, virtually identical proportions. Grahame (1984) reported that patients with late paraphrenia (schizophrenia of old age) were less likely to show some of the first-rank symptoms (particularly thought insertion and withdrawal) than younger schizophrenics. However, nearly 60% of his patients, all of whom were over the age of 60, had at least one first-rank symptom, a proportion which is no different from that reported in younger schizophrenics.

Next, it might be argued that it is inappropriate to use acute organic psychotics as a subject group because the claims about the similarity between schizophrenia and organic conditions have been made with chronic organic states (e.g. temporal lobe lesions (Flor-Henry, 1983) and birth injury (Murray *et al*, 1985)). This criticism is difficult to refute, and indeed it is undoubtedly true that some chronic organic psychoses (e.g. alcoholic hallucinosis (Cutting, 1978), epileptic psychosis (Toone *et al*, 1982)) are phenomenologically identical to schizophrenia, with no apparent organic basis. One can question, however, whether schizophrenia as diagnosed, for example, by DSM-III criteria, is *too* broadly conceived. If organic psychosis does indeed produce a characteristic set of phenomena, then this should lead to more refined criteria for 'familial' or 'sporadic' schizophrenia. It should then be possible to demonstrate that DSM-III criteria encompass a heterogeneous collection of psychoses. In this respect the study of acute organic psychosis would be justified as helping to delineate the boundaries of organic and 'functional' psychoses.

It could also be argued that it is inappropriate to use schizophrenics as a control group if the issue in question is the boundary between organic and functional psychotic phenomena. A better control group might have been a consecutive series of non-organic psychotics, including manics, depressive psychotics and paranoid psychotics as well as schizophrenics. This heterogeneous control group was employed in an earlier study (Cutting, 1980), and even fewer functional psychotics than in the current schizophrenic sample had the common organic delusional themes of imminent misadventure to others or bizarre happenings in the immedate vicinity. The present control group was chosen in this study because the main issue addressed was differences between a symptomatic organic psychosis and schizophrenia.

Main findings

Of the four areas of psychopathology examined – delusions, perceptual disturbance, formal thought disorder and emotional disorder – the least useful in differentiating acute organic and schizophrenic psychosis was a disorder of emotion. This is not surprising, considering that neither condition incorporates this as a major diagnostic criterion, if one excludes flattening or inappropriate affect, which was found to be rare in first-admission schizophrenics. Lability of emotions was the most reliable indicator of an organic psychosis, but was neither particularly specific nor sensitive to the condition.

The form of the perceptual disturbance was relatively specific to each condition. Visual hallucinations occurred in 34% of acute organic psychotics (people in 22% and animals in 15%) and only 16% of schizophrenics (people in 3% and animals in 1%). Auditory hallucinations, on the other hand, occurred in 34% of schizophrenics (all voices) but in only 18% of organic psychotics (voices 15%). Unknown voices in the second or third person, commenting, arguing, instructing or echoing thoughts, were the best discriminator, occurring in 22% of schizophrenics and only 4% of organic patients. In this study misidentification of persons was confined to organic psychotics, occurring in 14% of patients, although it is not unknown in acute schizophrenia (Cutting, 1985).

Formal thought disorder was common, occurring in 64% of organic patients compared with 31% of schizophrenics. Although there was a suggestion that the patterns in the two groups of patients were different, it was difficult to confirm this, because the scales used had been devised for schizophrenics and depressives, and the categories reflected this. For example, 19% of the organic psychotics were apathetic, responded monosyllabically to questions and complained of subjective confusion. The nearest category in Andreasen's scheme was poverty of speech, which, although rare in acute schizophrenics in this study, occurred in 22% of Andreasen's depressed subjects. Of the organic psychotics, 20% gave absurd answers to questions on orientation, most of which could not be attributed to inattention, amnesia or perceptual disorder. These were placed within the category of illogicality. Although not seen to this degree in acute schizophrenics in this study, this abnormality was noted in 27% of Andreasen's acute schizophrenics. The most striking abnormality in organic patients, although it was only seen in 8%, was the occurrence of intermittently irrelevant comments in the course of an otherwise fairly lucid conversation. This was categorised as tangentiality, although it appeared to lack the subtle links which mark the speech of schizophrenics. In summary, the thought disorder of organic patients appeared to have a quality which set it apart from that seen in the major functional psychoses, although how this should be categorised remained unclear.

The most surprising finding in the study was the common themes discerned in the delusions of organic patients, and the difference from those characteristically seen in schizophrenia. Not surprisingly, first-rank symptom delusions were very rare, and paranoid and mood-congruent delusions were common; but the most striking finding was that nearly a quarter of organic patients and nearly half of all the deluded organic patients shared a common theme of *imminent misadventure to others* or *bizarre happenings in the immediate vicinity*. This was rarely encountered in schizophrenics. The core feature appeared to be the enactment of some tragedy or misdeed by others, with the self a helpless onlooker, whereas in schizophrenics, even when similar themes occurred, the self was intimately involved. There are several explanations for this common theme. The delusions might have had a basis in misperception of events in the environment; this, however, is not an adequate explanation as the events tended to be outside the patient's immediate surroundings. Another possibility is that the delusions were confabulatory phenomena, with fluctuating amnesia the basic ingredient. This also cannot have been true for all delusional themes, because the events were in the main fantastic and implausible and were not mere filling-in of memory gaps (e.g. hospital floating on water, husband and friend underneath bed). One plausible and general explanation is that the delusions are a form of dream-like thinking. This would fit Lipowski's (1980) view of delirium as 'a disorder of wakefulness . . . with vivid dreams, nightmares, and oneiric or dreamlike mentation'. The absurd content of the delusions is also reminiscent of the thematic material in dreams, as described by Freud (1900) and others.

In conclusion, the phenomenology of an acute organic psychosis bears little resemblance to that of acute schizophrenia. There are therefore grounds for believing that if acute schizophrenia is due to organic causes then these must have a very different effect from the way in which an acute organic psychosis is brought about.

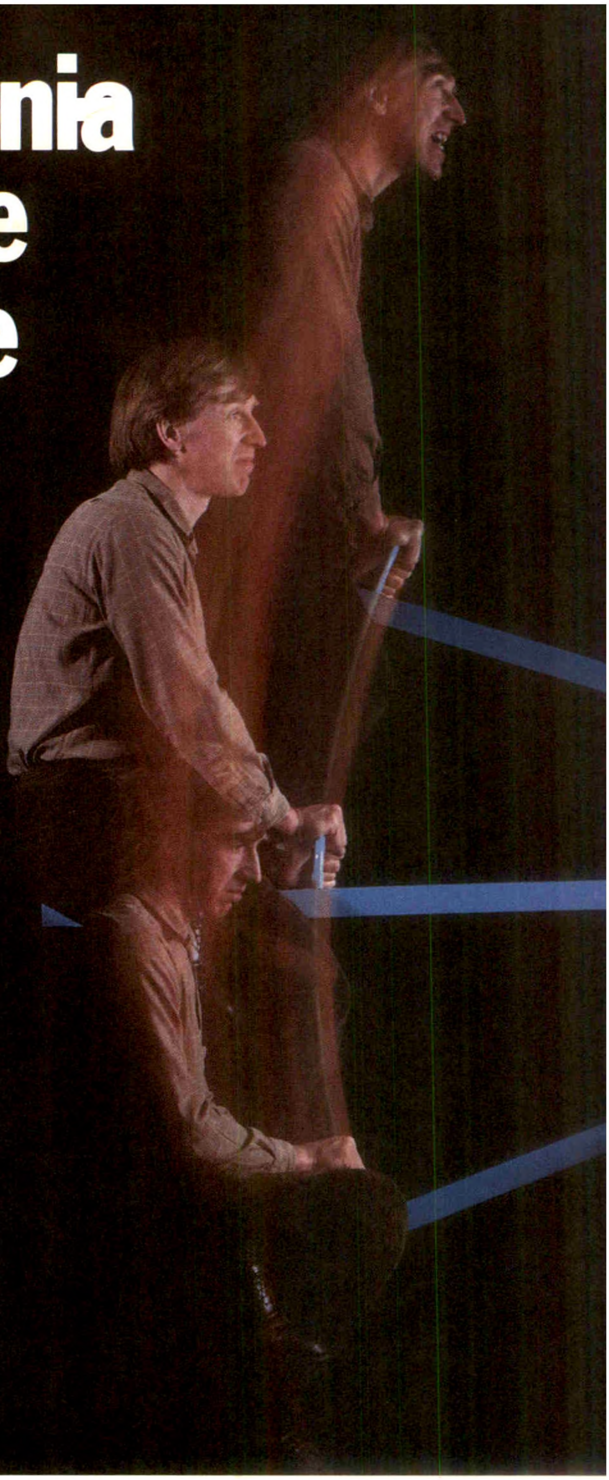
Schizophrenia therapy: the importance of balance



Too often, neuroleptic therapy swings the mood of the schizophrenic patient too far. Withdrawn patients' moods can be raised so high that they become agitated; whilst agitated patients may sink so low that they become withdrawn.

Experience shows that Piportil Depot treatment usually gets this critical balance right. Successful resocialization has been achieved even in patients who respond poorly to other neuroleptics.[1]

Piportil Depot contributes to putting the patient back into everyday life in other ways, too. Thanks to its relative freedom from extra-pyramidal effects,[2-5] and because injections need only be given every four weeks, patients hardly know they are being treated.

Piportil
DEPOT PIPOTHIAZINE PALMITATE

Piportil Depot Prescribing Information
Dosage: *(Adults)* Initially 25mg (0.5ml) by deep intramuscular injection into the gluteal region to assess susceptibility of patient. Dosage should be increased by increments of 25 to 50mg at appropriate intervals until a satisfactory response is obtained. Most patients respond to a dose of 50-100mg (1-2ml) every 4 weeks. Patients should be stabilised under psychiatric supervision. **Contra-indications:** Marked cerebral atherosclerosis, phaeochromocytoma, renal or liver failure, severe cardiac insufficiency or hypersensitivity to other phenothiazine derivatives. **Precautions:** A history of convulsive disorders or marked extra-pyramidal reactions to oral phenothiazines, in pregnancy and lactation. **Side-effects:** Reversible extra-pyramidal reactions, sleep disturbance, depression, blurred vision, asthenia, impotence, dry mouth, nausea, amenorrhoea, galactorrhoea, hypotension, hyperhydrosis and weight gain have been observed occasionally. Corneal or lenticular cloudiness have not been observed with Piportil alone, but in treatment with phenothiazine preparations in high dosage over a long period, there is a risk of such side-effects occurring. Local reactions at site of injection are rare. **Presentations and Hospital Prices:** Boxes of 10 x 1ml (50mg) £48.33 and 10 x 2ml (100mg) £79.08½ ampoules (PL0012/0117). **References:** 1. CLOPIXOL®

zuclopenthixol dihydrochloride/decanoate

TABLETS • INJECTION • CONC INJECTION

PRESCRIBING INFORMATION
CLOPIXOL TABLETS contain zuclopenthixol dihydrochloride.
Indications Psychoses.
Dosage and Administration The usual initial dose is 20-30mg/day, increasing as necessary to a maximum of 150mg/day, in divided doses. The usual maintenance dose in chronic schizophrenia is 20-50mg/day in divided doses. Not recommended for children.
Side-effects Extrapyramidal side-effects may occur and sometimes may require control by anti-Parkinson drugs.
Contraindications Acute alcohol, barbiturate or opiate poisoning. Intolerence to other neuroleptics. Pregnancy (relative). Use with caution in patients with Parkinsonism, severe arteriosclerosis, senile confusional states; serious renal, hepatic or cardiovascular disease.
Overdosage Overdosage should be treated by gastric lavage.
Package Quantities and NHS Price (correct at time of printing) Bottles of 100 Clopixol Tablets 2mg £3.05, bottles of 100 Clopixol Tablets 10mg £7.50, bottles of 100 Clopixol Tablets 25mg £15.00.
PL Nos 0458/0027,0028,0029. PA Nos 115/5/3,4,6.

CLOPIXOL INJECTION & CLOPIXOL CONC. INJECTION contain zuclopenthixol decanoate 200mg/ml and 500mg/ml respectively in thin vegetable oil.
Indications Psychoses, especially schizophrenia.
Dosage and Administration 200-500mg every 2-4 weeks by deep intramuscular injection.
Not recommended for children.
Side-effects Early (frequent) and late (rare) dyskinesias. Extrapyramidal effects sometimes require dose reduction or anti-Parkinson treatment.
Contraindications Comatose states.
Precautions Caution in patients with advanced renal, hepatic, or cardiovascular disease, Parkinson's disease, pregnancy, car driving or machine operation.
Further Information Overdosage should be treated by (a) anticholinergic anti-Parkinson drugs if extrapyramidal symptoms occur. (b) By sedation (with benzodiazepines) in the unlikely event of agitation or excitement. (c) By noradrenaline in saline intravenous drip if the patient is shocked.
Package Quantities & NHS Price (correct at time of printing) 10 x 200mg (1ml) ampoules £30.14, 1 x 200mg (10ml) vial £28.63, 5 x 500mg (1ml) ampoules £36.23.
PL Nos 0458/0017,0041. PA Nos 115/5/1,5,7

Haloperidol Decanoate *v*. Fluphenazine Decanoate as Maintenance Therapy in Chronic Schizophrenic In-patients

J. P. McKANE, A. D. T. ROBINSON, D. H. WILES, R. G. McCREADIE and G. S. STIRLING

In a double-blind study of 38 chronic schizophrenic in-patients, haloperidol decanoate was compared with fluphenazine decanoate as maintenance therapy over 60 weeks. Both drugs were given by injection at 4-week intervals. Haloperidol and fluphenazine were assumed to be equipotent; the mean starting dose of the former was 127 mg and of the latter 106 mg. The number of withdrawals over 60 weeks was similar in both groups but relapses, strictly defined, were significantly more frequent in the haloperidol group. When patients were switched to haloperidol, Parkinsonism diminished more quickly than in the fluphenazine group, but after 60 weeks there was no difference in severity in the two drug groups. The higher relapse rate and the quicker reduction in Parkinsonism in the haloperidol group might be due to a misjudgement in equivalent doses of the two drugs. Plasma haloperidol steady state levels were reached in most patients by 8–12 weeks. Plasma neuroleptic and prolactin levels, week-by-week systemic drug availability and Parkinsonism showed less variation between injections with haloperidol than with fluphenazine.

Haloperidol decanoate was introduced into the United Kingdom in 1982 for use primarily as maintenance therapy in chronic schizophrenics. Although oral haloperidol has been widely investigated (Ayd, 1980), there have been only four published double-blind controlled studies comparing haloperidol decanoate with other active medication in schizophrenic patients (Chouinard *et al*, 1984; Wistedt *et al*, 1984; Kissling *et al*, 1985; Bechelli *et al*, 1985). The principal drawback in these studies was the short follow-up period: 5–8 months. Firstly, the present study examines, over a 60-week period, the efficacy and Parkinsonian side-effects of haloperidol decanoate when used as maintenance therapy in chronic schizophrenic in-patients, by comparing it with fluphenazine decanoate; and, secondly, as an injection interval of 4 weeks is recommended by the manufacturer, the study examines plasma haloperidol levels and week-by-week systemic drug availability.

Method

Patient selection

All in-patients in the hostel and long stay non-geriatric wards of Crichton Royal Hospital, Dumfries, were considered ($n = 180$). A patient entered the study if (a) he (or she) was physically fit; (b) he fulfilled the criteria of Feighner *et al* (1972) for definite or probable schizophrenia; (c) in the opinion of medical and nursing staff he was well controlled on and benefiting from antipsychotic medication; (d) he, and where traceable, his next of kin, gave consent. The criteria were fulfilled by 38 patients – 22 men and 16 women; their mean age was 56 years (range 31–71 years) and mean length of illness 31 years (range 10–50 years).

Medication

With the stipulation that equal numbers should receive each drug, patients were randomly and blindly allocated to injections every 4 weeks of haloperidol decanoate or fluphenazine decanoate; thus 19 patients received haloperidol and 19 fluphenazine. The starting dose of the latter was the approximate therapeutic equivalent of the previously prescribed neuroleptic (Davis, 1976; Wyatt & Torgow, 1976; British National Formulary, 1984); the haloperidol dose was calculated on the assumption that 1 mg haloperidol was equivalent in potency to 1 mg fluphenazine (as suggested by Suy *et al*, 1982). For the first 12 weeks, the 'run-in period', thioridazine at a dose of up to 100 mg four times a day could be added if a patient's mental state or behaviour deteriorated. Where this happened, the next dose of haloperidol or fluphenazine was increased by an amount equivalent to the additional thioridazine required. In this way, it was intended that patients would enter the 'study proper' on an adequate and appropriate dose. If a patient was still receiving thioridazine at the end of the run-in period, he did not immediately proceed to the study proper, but had subsequent doses of study medication increased until stabilisation of mental state and behaviour was achieved. After the 12-week run-in period, the study proper lasted a further 48 weeks.

Anti-Parkinsonian medication could be prescribed if Parkinsonism was rated as more than 'mild' (see below).

Assessment

Before the run-in period, week 0, and at weeks 4, 8, 12 (the beginning of the study proper), 28, 44 and 60, and at the time of any relapse, one of two psychiatrists assessed the patient's mental state by the Krawiecka Scale (Krawiecka *et al*, 1977), Parkinsonism by the Simpson & Angus Scale (Simpson & Angus, 1970) and a global five-point scale (0 = absent, 1 = doubtful, 2 = mild, 3 = moderate, 4 = severe), and tardive dyskinesia (TD) by the AIMS Scale (US Department of Health, Education and Welfare, 1976). Akathisia was not assessed. Nurses assessed behaviour by the Wing Ward Behaviour Scale (Wing, 1961). To assess inter-rater agreement, 12% of mental state ratings ($n = 26$, from 18 different patients), 8% of Parkinsonism ($n = 45$, from 24 patients) and 7% of TD ratings ($n = 42$, from 25 patients) were made independently by both psychiatrists. Patients were weighed and injection sites were examined at regular intervals.

A patient was deemed to have relapsed if after entry into the study proper there was a deterioration in mental state or behaviour which required thioridazine at a dose of 100 mg four times a day for more than one week. It was the decision of the consultant psychiatrist who was responsible for the patient's care, and who was blind to which drug the patient was receiving, to prescribe thioridazine after discussion with other medical and nursing staff.

Blood samples were taken immediately before an injection at regular intervals over the 60 weeks to measure plasma haloperidol and fluphenazine levels by radioimmunoassay techniques (Wiles & Franklin, 1978), full blood count and liver function tests. Also, to study in detail between-injection plasma neuroleptic and prolactin levels, blood samples were taken from six patients in each drug group immediately before the eighth injection, and then 2, 4, 6, 8, 12 and 24 hours, and 3, 7, 14, 21 and 28 days later. At each sample time, Parkinsonism was assessed by the Simpson & Angus Scale.

Results

At week 0 there were no statistically significant between-group differences in age, sex distribution, and severity of illness and side-effects as measured by the Krawiecka, Wing, Simpson & Angus and AIMS scales (Table I). The mean monthly doses of haloperidol and fluphenazine decanoate at week 0 were 127 mg and 106 mg respectively; and at week 12, 120 mg and 105 mg. Inter-rater agreement on mental state assessment was high (product-moment correlation coefficient $r = +0.85$, $P < 0.001$) as was that on Parkinsonism ($r = +0.90$, $P < 0.001$) and that on TD ($r = +0.80$, $P < 0.001$).

Run-in period

Five patients, two on haloperidol and three on fluphenazine, did not proceed to the study proper: it was impossible to discontinue thioridazine in one patient, a second withdrew, a third became physically ill, a fourth (on fluphenazine) committed suicide, and a fifth developed an acute anxiety state after the suicide. Three patients on haloperidol and four on fluphenazine required thioridazine. Eight patients on haloperidol and ten on fluphenazine required anti-Parkinsonian drugs. In the 33 patients who entered the study proper, Parkinsonism as measured by the Simpson & Angus Scale was significantly less in the haloperidol than the fluphenazine group at the end of the run-in period (t test, $P < 0.01$).

Study proper

Seventeen patients on haloperidol and 16 on fluphenazine entered the study proper.

Relapsers

Significantly more patients on haloperidol relapsed (6 of 17 on haloperidol, 35%; 1 of 16 on fluphenazine, 6%; Fisher's Exact Probability Test, $P < 0.05$). One relapser on haloperidol committed suicide. The monthly dose of haloperidol decanoate at weeks 0 and 12 in the relapsers was 153 mg and 173 mg respectively, compared with 92 mg at both time points in the 11 patients from the haloperidol group who completed the study.

Non-relapsers

Eleven patients on haloperidol and 12 on fluphenazine completed 60 weeks of treatment. Three of the 15 non-relapsers on fluphenazine were withdrawn for other reasons: two refused medication, one developed severe akathisia. At the end of the study the mental state of the 11 patients on haloperidol decanoate was better than that of the 12

TABLE I
Initial severity of illness and side-effects

	Haloperidol group			*Fluphenazine group*		
Rating	*Mean score*	*Standard deviation*	*Range*	*Mean score*	*Standard deviation*	*Range*
Krawiecka total score	8.5	5.0	1–18	8.2	5.4	1–21
Wing total score	5.5	4.1	0–14	4.8	4.4	0–18
Simpson & Angus total score	3.5	3.2	0–12	4.0	3.0	0–10
AIMS total score (items 1–7)	4.6	5.1	0–20	2.9	2.9	0–9

patients on fluphenazine, and ward behaviour in the former group worse (t tests, both $P<0.05$). There were no other statistically significant between- or within-group differences in scores on mental state, behaviour and TD scales.

There were no significant between-group differences in Parkinsonism scores at the end of the study. At some time during the 48-week study proper, eight patients on haloperidol and eight on fluphenazine required anti-Parkinsonian drugs.

After 60 weeks' treatment, there were no significant changes in weight, full blood count or liver function tests. No abnormalities were noted at the site of injection in either treatment group.

TABLE II
Number of patients in each drug group at different stages of the study

	Number of patients receiving haloperidol decanoate	*Number of patients receiving fluphenazine decanoate*
Entry to study	19	19
End of run-in period	17	16
End of study proper	11	12

Plasma neuroleptic levels

(Full details of plasma neuroleptic levels are available on request to RGMcC.)

Plasma haloperidol levels in the 11 patients who completed the study suggest steady state levels were reached in most patients 8–12 weeks after the first injection; t-tests showed there was no statistically significant rise in mean plasma levels when compared with the previous month after week 8. However, in one patient the level was still rising between weeks 44 and 60 and in another between weeks 28 and 44. In the fluphenazine assay, cross-reactions with previously prescribed neuroleptics, especially flupenthixol decanoate and clopenthixol decanoate, made interpretation of plasma 'fluphenazine' levels in the first months of the study impossible, and thus time to reach steady state could not be estimated.

Mean plasma neuroleptic and prolactin levels and Parkinsonism scores were studied in detail in the two subgroups over a 4-week period after the eighth injection. In the fluphenazine group there were significant differences over time in plasma fluphenazine and prolactin levels and Simpson & Angus total scores (F tests, all $P<0.01$). The differences were due to higher measurements in the first few days after injection. No such differences were found in the haloperidol group. There were also significant ($P<0.01$) positive relationships between plasma levels and both prolactin levels and Simpson & Angus scores in the fluphenazine group, but no significant linear relationships in the haloperidol group. There were no significant between-group differences in prolactin levels. Systemic drug availability as measured by the area under the plasma level/time curve was more consistent week-by-week in the haloperidol group; in the fourth week after injection, systemic availability was 85% of that found during the first week, whereas in the fluphenazine group it was 63%.

Discussion

The study examined chronic schizophrenic in-patients previously well maintained on antipsychotic medication. Such patients do not have to face the stresses of life outside hospital and therefore are less likely to relapse (Leff & Vaughn, 1980). A more rigorous test of the comparative efficacy of haloperidol and fluphenazine decanoate would be to examine their use in out-patients or day-patients. Nonetheless, 35% of patients receiving haloperidol relapsed over a 48-week period, a figure significantly higher than that for fluphenazine. There are several possible explanations for this difference in relapse rates. Firstly, haloperidol decanoate may be less effective than fluphenazine decanoate as maintenance therapy. Secondly, the dose of haloperidol may have been too low. In calculating the starting dose it was assumed to be equipotent with fluphenazine. Previous studies have assumed a haloperidol/fluphenazine dose ratio of 1.4:1 (Wistedt *et al*, 1984) or 3:1 (Chouinard *et al*, 1984). It is noteworthy, however, that in the 12-patient subgroup in the pharmacokinetic study there was no significant between-group difference in plasma prolactin levels, a measurement of dopamine blockade, in patients on haloperidol decanoate and fluphenazine decanoate receiving broadly similar amounts of drug. Finally, relapse in the present study was strictly defined. If withdrawal rates for *all* reasons over the 60 weeks are compared, then the significant difference disappears (42% on haloperidol, 37% on fluphenazine).

Although at the end of the study there were no significant between-group differences in Parkinsonism, Parkinsonism diminished more quickly in patients switched from the previously prescribed neuroleptic to haloperidol decanoate than in those switched to fluphenazine. This again may be a dose effect. Where the haloperidol/fluphenazine dose ratio was higher than in the present study (Chouinard *et al*, 1984) there was no between-drug difference in extrapyramidal side-effects; where the ratio was similar (Wistedt *et al*, 1984) anti-Parkinsonian medication was used less in the haloperidol decanoate group.

The time to reach plasma haloperidol steady state levels in most patients, 8–12 weeks, was broadly similar to that in other studies (Derberdt *et al*, 1980; Reyntjens *et al*, 1982). However, in one patient at least, plasma levels were still rising after 44 weeks of treatment. The reason for this is not clear, although it is noteworthy this patient was receiving the highest dose of haloperidol decanoate, 325 mg at 4-week intervals. Perhaps in patients on high doses a 4-week interval between injections is too short.

Injections at 4-week intervals produced flatter plasma neuroleptic/time curves and a more consistent week-by-week systemic drug availability with haloperidol than with fluphenazine. The clinical significance of this is not clear, as the relapse rate with fluphenazine was lower. There is as yet no information as to what plasma level of haloperidol or fluphenazine should be achieved before the chance of relapse is substantially reduced. However, an increase in plasma fluphenazine levels in the first few days after injection was associated with an increase in Parkinsonism.

Acknowledgements

We wish to thank patients and nursing staff for their co-operation; Janssen Pharmaceutical for financial and other assistance; Mrs Anne Whitehead for statistical advice; and Miss Pamela Cowan for secretarial assistance.

Prescribing Information ▼ Presentation: Round, yellow, enteric-coated tablets each
ig 50mg fluvoxamine maleate, imprinted with 'Duphar 291'. Pack of 60 tablets, basic NHS price
Uses: Treatment of those affective disorders characterised by persistent low mood, impaired
iotor activities and psychosomatic complaints. **Dosage and Administration:** The tablets should
owed without chewing and with water. Adults: The effective daily dose usually varies between
nd 200mg and should be adjusted to the individual response of the patient up to a maximum of
The minimum recommended starting dose is 100mg given in the evening. A total daily dosage in
f 100mg should be given in divided doses. Elderly: The same dosage regimen may be utilised in the
s in the general population. Children: There are insufficient data to recommend the use of Faverin in
Contra-indications, Warnings, etc: Faverin should not be given together with or within two
of terminating treatment with monoamine-oxidase inhibitors. Patients with hepatic or renal
ency should begin treatment with a low dose and be carefully monitored. Faverin has no effect on
otor skills associated with driving and operating machinery. However, in combination with alcohol
pairment may be seen. Use in pregnancy and lactation: There has been little human use but there
no adverse animal evidence. Avoid in pregnancy and in nursing mothers if a better known and safer
ve is available, although safety in pregnancy is likely. Interactions with other drugs: In interaction

studies increased plasma levels of propranolol and warfarin were seen during concurrent administr
Faverin. Care should be taken when Faverin is prescribed to patients already receiving propran
warfarin as the dose of these drugs may need to be lowered. No interactions were seen with digoxin
atenolol. **Side-effects:** The commonest symptom observed with Faverin administration is nausea
usually diminishes early during the course of treatment. Other treatment emergent symptoms r
during clinical studies were somnolence, constipation, agitation, anorexia and tremor. Other reported
are often associated with the illness and their incidence in controlled trials is comparable
experienced with placebo. Faverin may cause a decrease in heart rate. During treatment, limited cha
repolarization were observed in the ECG, but no causal relationship could be demonstrated. The incid
postural hypotension was similar to that seen in patients treated with placebo. Treatment of overdosa
specific antidote is known. The stomach should be emptied as soon as possible after tablet ingest
symptomatic treatment should be given. The use of medicinal charcoal is also recommended. **Pa**
Quantities 50mg tablets: available in packs of 60 (3 strips of 20 blister-packed tablets). **Product L**
Number 50mg tablets: 0512/0070. Further information is available from: Duphar Laboratories

Faverin.® Specific action on brain metabolism may explain its many dvantages in the treatment of depression

FAVERIN®

fluvoxamine

Highly Selective 5-HT Reuptake Inhibitor

So what has Lilly ever done for Britain?

Well, where should we start?

The Second World War seems as good a place as any. By 1942 around one third of the production capacity of our newly-built Basingstoke factory was devoted to producing medicines for Britain's armed forces.

From foot powders to burn treatment, products manufactured by Lilly played their part in Britain's war effort.

Today we are contributing more than ever to Britain.

Our Part in Building Basingstoke

In 1939 we opened our first manufacturing plant in Britain, at Basingstoke. In those days the town had a population of less than 20,000. Today it is a busy commercial centre of 90,000 people.

As one of Basingstoke's biggest and longest-established employers, we are proud of our role in the town's growth and current success.

Just the Job for Liverpool

At Speke on Merseyside, our antibiotics processing plant provides much needed jobs for 900.

In fact, our Speke General Manager was recently awarded an OBE for his 'outstanding contribution to alleviating the problems of Merseyside.'

Add in our other UK operations, including our research centre in Surrey, and Lilly Industries Limited employs over 2,000 people throughout Britain.

The Health of the Nation

Leaving aside our contribution to the economy's well-being, we also do a considerable amount for the nation's health.

As one of the world's leading pharmaceutical companies, we have discovered and developed numerous important drugs.

An Indispensable Discovery from Lilly

It was Lilly who pioneered the Vinca Alkaloid group of compounds. These are widely used in Britain in the treatment of childhood leukaemia and are described by the Oxford Textbook of Medicine as 'indispensable.'

Thanks in part to this discovery, a condition that once almost always condemned young sufferers to death now has a vastly improved prognosis.

Then there was our work in the development of oral antibiotics. Before their introduction, administering antibiotics was a laborious and costly process. Expensive for the NHS and painful for the patient. With our help, the discomfort of both parties has been considerably lessened.

More recently, in 1982, we introduced genetically engineered human insulin manufactured in our plant in Speke. The benefit to patients with diabetes in Britain and around the world is unquestionable.

Where Research Becomes Reality

The success of our products is based, to a great extent, on research. UK research personnel located at our Erl Wood Research Centre in Surrey have contributed greatly to many of our worldwide projects, a prime example of Britain's expertise in the pharmaceutical field.

Exporting to the World

Lilly Industries Limited ranks among Britain's top exporters. Products manufactured here are distributed around the world, netting millions for Britain's balance of payments each year.

And what of profits? As an American company, do all the financial benefits wing their way back across the Atlantic? Not at all.

Investing in Britain

Our investment in Britain now tops over £140 million. In the last five years alone we have ploughed back £80 million. What is more, with our continued commitment to innovative pharmaceutical fields such as rDNA technology, we'll be spending a lot more in Britain in the next few years.

Employment, economic growth, investment and expertise. Just a few of the things an American pharmaceutical company has done for Britain.

A Controlled Comparison of Fluoxetine and Amitriptyline in Depressed Out-patients

J. P. R. YOUNG, A. COLEMAN and M. H. LADER

Fluoxetine, a selective serotonin uptake inhibitor (mean dose 73 mg each morning) was compared with amitriptyline (mean dose 122 mg at night) in a double-blind study of 64 depressed out-patients. Fifty patients completed the 6-week trial. The drugs did not differ with respect to psychiatrists' ratings, but amitriptyline was slightly superior with respect to patients' ratings. The amitriptyline-treated group had complaints of dry mouth and dizziness on standing; the fluoxetine-treated group of sleep disturbances, nausea, and headaches.

Fluoxetine is a potent, selective inhibitor of 5-hydroxytryptamine (5HT, serotonin) (Wong *et al*, 1974, 1975). Unlike many other selective inhibitors such as clomipramine, fluoxetine does not lose selectivity when metabolised to desmethylfluoxetine (Fuller *et al*, 1978). Because of this selectivity it has been extensively evaluated as a possible antidepressant with a low incidence of unwanted effects (Wernicke, 1985). An extensive series of studies have been carried out to compare the efficacy and safety of fluoxetine to those of placebo, imipramine, amitriptyline, and doxepin (Stark & Hardison, 1985). This brief account concerns a controlled double-blind comparison of fluoxetine with amitriptyline, conducted in a busy psychiatric out-patient department of a London teaching hospital.

Method

Physically healthy adult out-patients, aged 20–65, presenting with moderately severe unipolar depression (Research Diagnostic Criteria (RDC); Feighner *et al*, 1972) not requiring electric convulsion therapy (ECT) were eligible for inclusion. A minimum Hamilton Rating Scale for Depression (HRSD) score of 18 was required for recruitment. All patients with schizophrenia or organic features, or those who had been receiving antidepressant drugs or ECT during the 4 weeks before referral, were excluded. All patients were new referrals from general practitioners. Most patients entered were, however, taking sedatives or tranquillisers when first seen in the out-patient department. Successive patients who were suitable for drug treatment were allocated randomly either to fluoxetine or amitriptyline treatment for a period of 6 weeks.

Both drugs and placebo were identically formulated, each capsule containing 20 mg fluoxetine or 50 mg amitriptyline. The dose was limited during the first week to 40 mg fluoxetine in the morning plus placebo at night, or 50 mg amitriptyline at night plus placebo in the morning. During the remaining 5 weeks of the trial a flexible dosage schedule was used to allow 40–80 mg fluoxetine in the morning or 50–150 mg amitriptyline at night, depending on the clinical response and side-effects. Each patient was seen for initial assessment and after 1, 3 and 6 weeks of treatment.

A standard psychiatric history was taken at the first visit. At each visit the patient completed the Beck Scale for Depression (BSD) and two analogue self-assessment scales for depression and anxiety. An independent assessor scored the patient on the HRSD and the Hamilton Rating Scale for Anxiety (HRSA), and assessed the overall severity of the depression. The Beck Scale was also completed by the patient 3 days after entry to the trial. A standard form for rating side-effects was completed by the second psychiatrist, who also regulated drug dosage. This prevented knowledge of side-effects biasing the clinical ratings of the other assessor. On each visit the patient was weighed and ratings made for changes in appetite and for changes in sleep pattern, libido, and diurnal variation of mood and energy. Before starting treatment, and on completion of the trial, blood samples were taken for routine laboratory tests including haematology, renal, hepatic, and thyroid function.

Drop-outs

Of the 64 patients initially entered in the double-blind trial, 14 were withdrawn (seven in the fluoxetine group, seven in the amitriptyline group). The commonest cause (four in each group) was failure to re-attend. No amitriptyline and two fluoxetine patients dropped out because of side-effects (persistent sleep disturbances).

Pre-treatment matching of groups

The fluoxetine group comprised 25 patients (17 females, 8 males) with a mean age of 46.1 years. Five patients had a family history of affective illness; ten patients had experienced previous depressive episodes. In the amitriptyline group of 25 (17 females, 8 males) the mean age was 46.6 years; five patients had a family history of affective illness and ten patients had experienced depressive episodes. Before entering the trial, 15 patients had previously received tricyclic antidepressants. Of these, nine were given fluoxetine treatment and six received amitriptyline during the course of the trial. Analysis of variance showed no significant pre-treatment differences between the groups for any of the variables.

Dosages attained

The mean daily dosages by week 3 were 59 mg fluoxetine and 90 mg amitriptyline; by week 6 they were 73 mg and 122 mg respectively. No additional medication was prescribed apart from diazepam and temazepam in low dosage as daytime and night-time sedatives respectively. These were mostly continued from previous drug therapy. In the fluoxetine group, diazepam was prescribed for 21 patients (mean dosage 5.8 mg daily) and temazepam for 24 patients (mean dose 12.4 mg nightly). In the amitriptyline group, diazepam was given to 23 patients (6.5 mg) and temazepam to 23 patients (13.3 mg). There were therefore no major differences between the treatment groups.

Results

Change with treatment

Analyses of variance were carried out on the data from the rating occasions, differences between drug effects being obtained from the drugs × week interaction term. Mean scores on the HRSD and HRSA scales and on overall severity improved highly significantly during the 6 weeks of treatment, with no differences in efficacy between fluoxetine and amitriptyline. The HRSD items were grouped into those which were 'pure' depressive items and those that assessed concomitant anxiety, excluding those that could be affected by drug side-effects such as sleep and appetite. No differences between the drugs were found with respect to improvement in the depressive items. Patients were also rated at the end of the 6 weeks with respect to their degree of improvement. No differences were found between the drugs with respect to these categories.

Differences between the drugs reached significance with respect to weight and appetite (Table I), amitriptyline increasing but fluoxetine decreasing both variables.

The only clinical rating to show differences between the two drugs was the Beck Scale for Depression (Table I): the diminution with fluoxetine treatment was significantly less than that with amitriptyline. The 'pure' depressive items of the scale were grouped and analysed separately; no drug differences were found. Furthermore, the overall self-ratings did not show drug differences.

Unwanted effects

The number of patients at each assessment with ratings of each side-effect higher than at the pre-treatment assessment (treatment-emergent side-effects) was computed (Table II). Complaints of dryness of the mouth and of dizziness on standing up (postural hypotension) were significant in patients on amitriptyline – dryness of the mouth was marked throughout, hypotension at week 3 only. The only treatment-emergent side-effects rated by patients on fluoxetine were nausea, especially towards the end, and headache at week 1. Two of the patients initially entered into the trial dropped out because of side-effects – both were in the fluoxetine group and had sleep disturbances. No significant abnormalities in the laboratory tests were found.

Predictors of improvement

Family history of affective disorder, age, sex, and previous treatment with a tricyclic antidepressant in the current episode were evaluated as possible factors predicting response to fluoxetine or amitriptyline on the HRSD or HRSA scales. No relationship was found.

TABLE I
Comparison of fluoxetine and amitriptyline

Variable	*Drug*	*Pre-treatment*	*Time of examination 3 days*	*1 week*	*3 weeks*	*6 weeks*	*Drugs × weeks*	*Analysis of variance weeks*

Discussion

This trial was conducted in a busy out-patient department. Patients were referred by general practitioners or other consultants, and were usually already taking benzodiazepines to allay anxiety or to induce sleep, at the time their primary depressive illness was diagnosed. Current clinical practice is not to attempt to wean such patients from their benzodiazepine medication, because of the subsequent recrudescence of anxiety, rebound of anxiety, or even withdrawal problems. Instead, the existing medication was standardised, diazepam being established as the daytime anxiolytic and temazepam as the hypnotic, and the antidepressant added. It is noteworthy that there were no differences in numbers of patients receiving benzodiazepines, nor in average doses attained, despite amitriptyline's marked sedative properties. The benzodiazepine dosages in both groups were modest.

The patients met RDC criteria, and were typical of psychiatric department out-patients. Almost all had been ill for more than 6 months, but the initial HRSD scores were only around 26, suggesting persistent illnesses of moderate severity. A third of the patients had previously failed to respond to tricyclic antidepressants, but often the dosage had been low. In the present trial amitriptyline dosage averaged 122 mg by week 6 (a typical UK dosage), and fluoxetine averaged 73 mg, in agreement with most previous studies (e.g. Chouinard, 1985). Feighner (1985), however, used higher doses of amitriptyline (145–173 mg/day) and lower ones of fluoxetine (51–59 mg/day).

Efficacy was similar in the two groups, with the exception of the BSD, on which fluoxetine proved just significantly inferior to amitriptyline. However, analysis of the 'pure' depressive items showed no drug differences. Chouinard (1985) reported an identical finding with the Zung depression scale, and suggested that the sedative effects of amitriptyline may have been misperceived by the patients as therapeutic, whereas psychiatrists' assessments were relatively unbiased. However, most of our patients received sedatives as well, and the differences could therefore not be due to lack of sedation in the fluoxetine patients. In another trial (Feighner, 1985), self-ratings were more favourable for fluoxetine. Overall, both drugs proved to be effective antidepressants over the 6-week trial, with end-point values similar to most other efficacy trials (e.g. Stark & Hardison, 1985; Feighner, 1985).

The apparent efficacy of fluoxetine has some interesting implications for biochemical hypotheses of antidepressant actions. Fluoxetine has no effect on down-regulating noradrenergic or 5HT receptor function (Peroutka & Snyder, 1980), generally held to be related in some way to long-term antidepressant effects (Willner, 1985). Nor does it have the typical behavioural pattern in animals of an antidepressant (Stark *et al*, 1985).

The most obvious differences between the drugs concerned appetite and weight, which increased in the amitriptyline and decreased in the fluoxetine patients. In general, depressed patients lose appetite and weight, and treatment-related increases are to be welcomed. However, some patients increase their weight when depressed, and others complain that tricyclic drugs make them obese; in both these groups fluoxetine might have a particular utility. These effects of fluoxetine accord with the known functions of 5HT in the brain (Lemberger *et al*, 1985).

The assessment of side-effects in clinical trials is controversial, particularly with depressed patients who typically have many somatic symptoms related to the illness. No amitriptyline and only two fluoxetine patients dropped out because of side-effects. This contrasts with the Feighner (1985) trial, where the drop-out on amitriptyline was high, presumably because of the high dose. In the study we concentrated on symptoms which were significantly treatment-emergent. Amitriptyline patients complained of dry mouth throughout, and of dizziness on standing at the 3-week point. Nausea was the cardinal side-effect in the fluoxetine patients, affecting nearly half by week 6. This is the commonest side-effect generally reported (Wernicke, 1985).

In practical clinical terms both drugs proved equally efficacious, most patients showing moderate clinical improvement. For ethical reasons a placebo group could not be included, so the absolute usefulness of both drugs can only be assumed. Side-effects were less troublesome in the fluoxetine patients, but they did not rate themselves as improved as the other group. The curious discrepancy between observer and self-ratings needs more detailed evaluation.

THE DEPIXOL

cis(Z)-flupenthixol decanoate

DIFFERENCE

= Proven antipsychotic effect (1-7)

↑ Restores mood (1-3) ⌇ Dosage flexibility < Cost-effective therapy (8)

PRESCRIBING INFORMATION

Depixol Injection and Depixol-Conc. Injection contain cis(Z)-flupenthixol decanoate, 20mg per ml and 100mg per ml respectively, in thin vegetable oil.
Indications Psychoses, especially schizophrenia, particularly where there are associated features of withdrawal, inertia or apathy.
Dosage and Administration By deep intramuscular injection, 1-2ml every 2-4 weeks, to a maximum of 400 mg weekly. Children: Not recommended for children.
Side Effects Early (frequent) and late (rare) dyskinesias. Extrapyramidal effects sometimes require dose reduction or anti-Parkinson drug treatment.
Contra-indications Not recommended for overactive patients, or for those with Parkinsonism, severe arteriosclerosis, senile confusional, or advanced renal, hepatic, or cardiovascular disease, intolerance to other neuroleptics, pregnancy.
Further Information Overdosage should be treated: (a) by anticholinergic anti-Parkinson drugs if extrapyramidal symptoms occur, (b) by sedation (with benzodiazepines) in the unlikely event of agitation or excitement, (c) by noradrenaline in saline intravenous drip if the patient is shocked.
Package Quantities & Basic NHS Prices Boxes of 10 x 20mg (1ml) £15.53, 10 x 40mg (2ml) £25.99, 10 x 100mg (1ml) ampoules £59.53, 5 x 20mg and 5 x 40mg syringes £8.51 and £13.74, 1 x 200mg (10ml) and 1 x 500mg (5ml) vials £14.74 and £28.27.

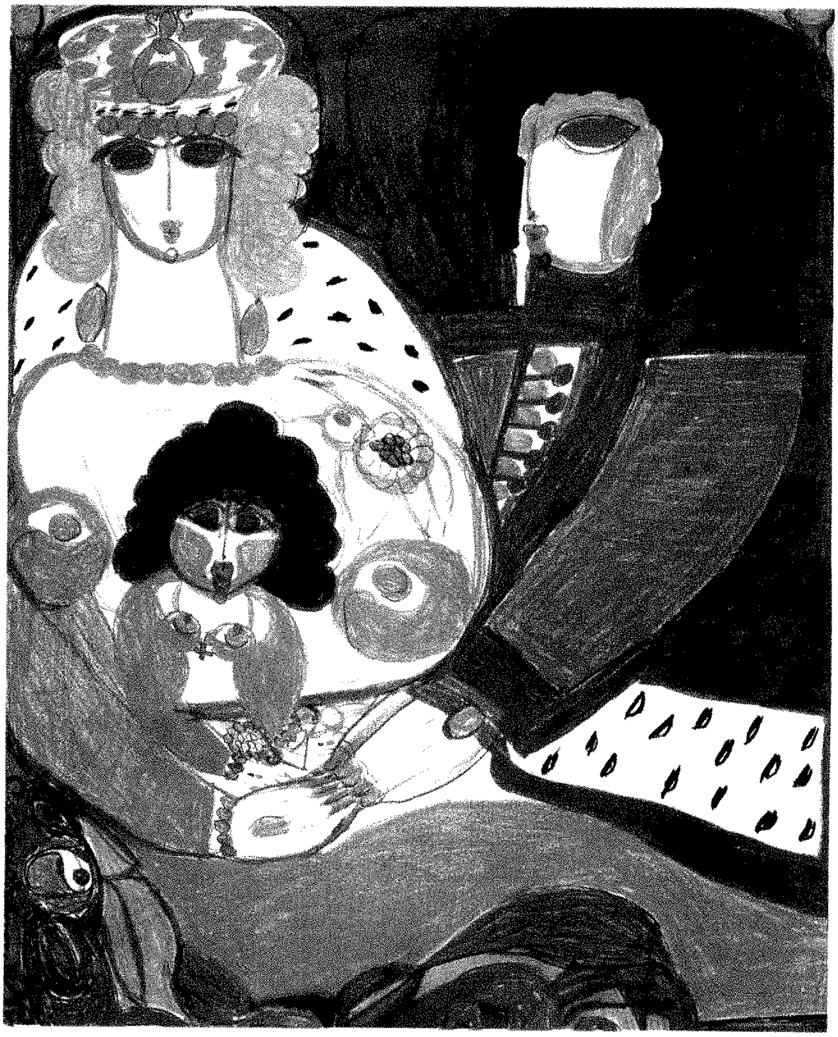
AN EXPRESSION OF SCHIZOPHRENIA.

Aloise was diagnosed as schizophrenic at the Cery Asylum, Lausanne. She was later transferred to the Asylum de la Rosiere where she remained for over 40 years until her death in 1964.

During the last 20 years of her life she worked steadily at her drawings.

The illustration below is produced with kind permission of the Musee Cantonal Beaux-Arts, Lausanne.



A TREATMENT.

Since the 1950s when Dr Paul Janssen and co-workers researched and developed the prototype butyrophenone haloperidol, it has become widely established throughout the world as an effective anti-psychotic. In 1982 Haldol* Decanoate was introduced to the UK as a depot neuroleptic with a consistent 4 week duration of action following a single deep intramuscular injection.

In mild symptomatology the dosage for Haldol* Decanoate is from 50-100mg given 4-weekly, whereas severe schizophrenic symptoms are usually controlled with up to 300mg.

The schizophrenic patient can benefit from a flexible therapy with little incidence of sedation[1] and a reduced requirement for antiparkinsonian medication[2] leaving him/her better able to participate in other forms of therapy.

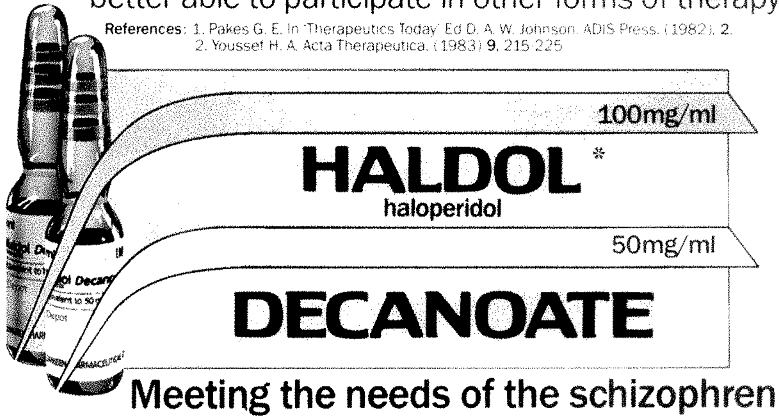
2. Youssef H. A. Acta Therapeutica. (1983) 9, 215-225



Meeting the needs of the schizophrenic.

Presentation: Straw coloured, viscous solution presented in 1ml brown glass ampoules equivalent to 100mg/ml haloperidol (as decanoate ester) and 1ml brown glass ampoules equivalent to 50mg/ml haloperidol (as decanoate ester) both in packs of 5. **Uses**: As a depot injectable form of haloperidol indicated for adults where long term maintenance treatment with a neuroleptic is required, for example in schizophrenia, other psychoses (especially paranoid) and other mental or behavioural problems where maintenance treatment is clearly indicated. **Side effects, precautions, contra-indications**: Haloperidol is not recommended during lactation. Use in Pregnancy: The safety of haloperidol in human pregnancy has not been established. Precautions: Caution in liver disease, Parkinson's disease, phaeochromocytoma, thyrotoxicosis, epilepsy and conditions predisposing to epilepsy. Antagonism of adrenaline, guanethidine, phenindione, anti-Parkinson effects of levodopa and impairment of metabolism of tricyclic anti-depressants have been reported. Haloperidol may increase the effects of CNS depressant drugs, and enhanced CNS effects when combined with methyldopa have been reported. Neurotoxic reactions to combined treatment with lithium and haloperidol have been reported. Side effects: In common with all neuroleptics, the following side effects may be observed, sedation, extra-pyramidal symptoms, tardive dyskinesia, mental dullness, dizziness, headache, excitement, agitation, insomnia, hyperprolactinaemia, galactorrhoea, gynaecomastia, oligo- or amenorrhoea, hypotension. Gastro-intestinal symptoms and weight changes have been reported. Anti-Parkinson agents should only be given as required. The elderly are more susceptible to sedative/hypotensive effects. Occasional local reactions such as erythema, swelling or tender lumps have been reported. In common with other anti psychotics, haloperidol has been associated with rare cases of neuroleptic malignant syndrome. **Dosage**: Haldol* Decanoate provides one month's therapy following a single deep intra-muscular injection in the gluteal region. An initial dose of 50mg every 4 weeks is recommended increasing if necessary after 2 weeks by 50mg increments to 300mg every 4 weeks. The dosage should be tailored to suit the individual patient and to reflect previous oral dosage. In adults 100mg Haldol* Decanoate is approximately equal to 500mg chlorpromazine (or equivalent) per day. Caution is required with the elderly, starting doses of 12.5mg to 50mg monthly should be tried first. **Product Licence Numbers**: 0242/0095, 0242/0094 **Basic NHS Cost**: 1ml x 100mg/ml x 5 £24.00 1ml x 50mg/ml x 5 £15.60. priadel® 200

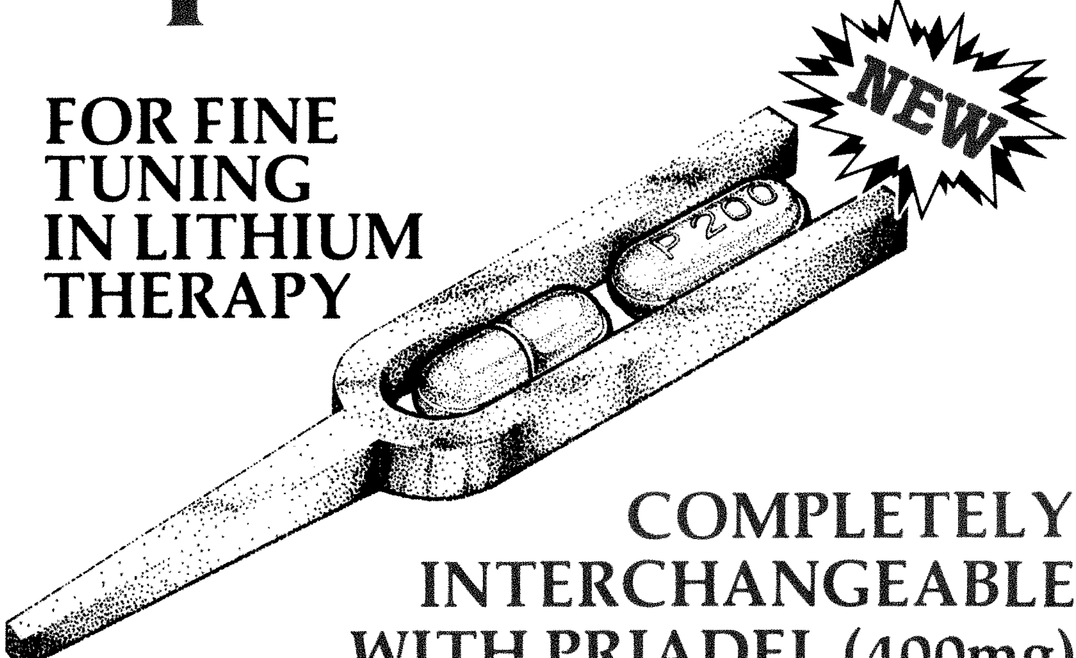
FOR FINE TUNING IN LITHIUM THERAPY



COMPLETELY INTERCHANGEABLE WITH PRIADEL (400mg) WITHOUT RE-STABILISATION

priadel® — the world's first controlled release lithium now offers maximum flexibility of dosage

---

PRESCRIBING INFORMATION

Presentation
Each Priadel 200 Tablet contains 200mg lithium carbonate Ph.Eur. in a controlled release formulation. Also Priadel Tablets each containing 400mg lithium carbonate in the same controlled release formulation.

Indications
Treatment and prophylaxis of all elements of affective illness. For the control of aggressive or self-mutilating behaviour.

Dosage
In patients of average weight (70kg) 400—1200mg daily as a single dose, usually on retiring. Check serum lithium level at least 12 hours after the last dose on day 4 or 5. The twelve-hour serum level should be in the range 0.7—1.0 mmol/l. Adjust dose where necessary and check serum lithium level weekly until stabilisation has been achieved.

Contra-indications, warnings etc.
Renal and cardiovascular insufficiency. Addison's disease and untreated hypothyroidism. Recommendation to discontinue Priadel before planned pregnancy and for the first trimester. Exercise care in circumstances where electrolyte balance may be disturbed due to concurrent infections or other medication, for example diuretics, appetite suppressants and steroids. See Data Sheet for reported possible drug interactions.

Side effects and precautions
Initiation of lithium therapy may give rise to transient side effects which usually disappear following stabilisation. These include fine hand tremor, weight gain, polydipsia, polyuria and anorexia. Nausea and diarrhoea which are related to the site and rate of absorption are minimised by the controlled release formulation of Priadel. Long-term treatment with lithium may be associated with disturbances of thyroid or renal function which should be monitored.

Toxic effects which may be indicative of impending lithium intoxication include: increasing anorexia, diarrhoea, vomiting, muscle weakness, lack of co-ordination, drowsiness or lethargy progressing to giddiness with ataxia, tinnitus, blurred vision, dysarthria, seizures and coma.

Product Licence Numbers

The Social Breakdown Syndrome in the Elderly Population Living in the Community: The Helping Study

T. S. RADEBAUGH, F. J. HOOPER and E. M. GRUENBERG

A representative sample of elderly people residing in the community was examined to establish their psychiatric status. An interview with a close friend or relative, focusing on a one-week period in 1981, was used to investigate each subject's functional limitations and troublesome behaviour, these being the two components of the Social Breakdown Syndrome. The data from the sample were weighted to allow estimates of the characteristics of the general population. No cases of SBS at its most extreme were identified, and almost the entire population was found to be functioning at an adequate or near-adequate level: all cases of severe SBS were attributable to troublesome behaviour. Severe SBS was shown to increase with age and to be most common in non-white males. Persons with dementing disorders were more likely than their non-demented counterparts to show severe/moderate SBS, but in the majority of cases of SBS there was no mental disorder.

The 'greying of America' is well under way, and the demographic changes which the USA will undergo in the next 20 years have been projected and described thoroughly by the Bureau of the Census (1977). The provision of medical care, health care and day-to-day care for this growing legion of elderly people is of increasing importance.

The scientific literature about elderly people is already massive, but there have been two important omissions from the research work: the first has been lack of attention to mental and neurological disorders and the consequences of such disorders; the second has been the failure to investigate populations of elderly persons living in the community. Much of the available information has been derived from persons seeking medical or social services: these are not necessarily representative of the elderly population as a whole.

Most elderly people do reside in the community: only 5% of those aged 65 or more reside in some type of long-term-care institution, although it is important to note this figure conceals extraordinary biases in colour, sex, and marital status. Most of the day-to-day care of ill and frail elderly people is thus provided not by organised medical, nursing or social services but by friends, relatives and neighbours who are often elderly themselves.

Method

Eastern Baltimore Mental Health Survey

The Eastern Baltimore Mental Health Survey (EBMHS) is attempting to fill some of the gaps in our knowledge about the life circumstances and day-to-day management of elderly people living in the community. It is an epidemiological field survey of the prevalence (Wave I) and incidence (Wave II) of mental disorders, and the patterns of health care and mental health care, in a geographically defined population, namely the residents of the eastern one-third of Baltimore City (Eaton *et al*, 1981).

For the EBMHS a representative sample of households was identified through a probability sampling plan, and all members of these households aged 18 or over were asked to participate in a lengthy structured interview containing the NIMH Diagnostic Interview Schedule (DIS). To screen for cognitive deterioration, the Mini-Mental State Examination (Folstein *et al*, 1975) was also included in the household interview, which was completed by 3481 people.

Every individual who scored poorly on the Mini-Mental State Examination or who responded in a particular (pre-specified) way to one or more key questions on the DIS (thus indicating possible mental disorder or cognitive deterioration) was offered an examination by a research psychiatrist. In addition, a randomly selected 17% of those who gave no such response suggestive of mental disorder or cognitive deterioration were invited to participate in either the *Standardized Psychiatric Examination* of Romanoski & Chahal (1981, unpublished) or a Clinical Reappraisal (Folstein *et al*, 1985*b*) which yielded diagnoses of mental disorder using DSM-III criteria. Table I contains a summary of responses to the various stages of the survey among those aged 65 or over, analysed according to sex and colour.

The Helping Study

Upon completion of the clinical reappraisal, individuals aged 65 or over ($n = 228$) were invited to participate in the 'Helping Study'. This required them to identify an informant, i.e. one of the people who were most familiar

TABLE I

Eastern Baltimore Mental Health Survey, Wave I (prevalence study): response rates for persons aged 65 or over, classified by sex and colour

	Whites		*Non-whites*

Invited to join Helping Study	59	87	37	45	228
Completed Helping Study	53 (90%)	79 (91%)	32 (86%)	38 (84%)	202 (89%)
Total population (estimated)	8769	14 122	2171	2689	27 751

with their day-to-day activities, who would agree to an interview. Informants were used to avoid relying on subjects with cognitive impairment for reports of their day-to-day affairs. However, some subjects served as their own informants: these people were either so isolated that no other individual knew the intricacies of their daily lives, or they were very concerned with privacy and did not want anyone to talk to an interviewer about them. There were 48 such cases.

The interview was of the non-schedule standardised type (Richardson *et al*, 1965), and averaged about 90 minutes in duration.

The Social Breakdown Syndrome

One of the principal questions we wished to answer for each subject in the Helping Study (with reference to a long list of activities necessary for living in the community) was:

> *"During the seven days prior to the interview, what did the subject do for him/herself?"*

The standard interview used with the informant to obtain an answer to this question is firmly rooted in the original work on the Social Breakdown Syndrome (Gruenberg *et al*, 1966). The Social Breakdown Syndrome (SBS) is characterised by a failure of social and personal care. It is thought to occur independently of specific psychiatric diagnoses (American Public Health Association, 1961) and is observed in a wide variety of illnesses and conditions. In fact, the SBS corresponds closely to the concept of 'disability' employed by the World Health Organization:

> In the context of health experience, a disability is any restriction or lack (resulting from an impairment) of ability to perform an activity in the manner or within the range considered normal for a human being . . . Disability is concerned with abilities, in the form of composite activities and behaviours, that are generally accepted as essential components of everyday life. Examples include disturbances in behaving in an appropriate manner, in personal care (such as excretory control and the ability to wash and feed oneself), in the performance of other activities of daily living, and in locomotor activities (such as the ability to walk). *(World Health Organization, 1980)*

The SBS has two dimensions: functional level (FL) and troublesome behaviour (TB) (Gruenberg *et al*, 1966). The *functional level* is defined on the basis of useful contributions of work around the house or yard, productive hobbies, recreation, reading or writing, and being able to be left alone. Subjects' *behaviour* was classed as *troublesome* if they required physical restraint; or needed assistance to eat, or to get in and out of bed; if they were incontinent or used a bedpan; if they attacked other people or made threats towards them; if they harmed themselves; or if they were mute or refused to speak. The Appendix describes in detail our classification of functional levels and degrees of troublesome behaviour.

The Helping Study data record was constructed on the general pattern of that used in the original work on SBS, but it was not an exact replica; e.g. it did not incorporate specific durations for the behaviour reported. The original SBS analysis revealed that people were rarely left alone for very short periods, so the SBS criteria for "was S left alone?" required that the subject was left alone for at least three hours. Thus the Helping Study data-recording procedures necessitated assuming that, if the subject was left alone, he or she was left alone for at least three hours.

Subjects

In summary: 228 individuals were invited to participate in the Helping Study, and an interview with the subject or an informant was obtained for 202 subjects. This sample differed from the general population aged 65 or more in Eastern Baltimore ($n = 277\ 751$) in terms of sex-, colour- and age-distribution; but knowing the response rate in each demographic sub-group (Table I) allowed us to weight the data from the sample to make it representative. Our sample also contained a disproportionate excess of individuals with a diagnosed mental disorder, due to our selection procedure, and we also weighted to compensate for this effect. Thus each of our subjects effectively represented a known but

TABLE II

Helping Study sample analysed (a) by sex and race, (b) by age, and (c) by diagnostic category; plus a projection of this analysis on to the elderly population of Eastern Baltimore

	Sample $n = 202$	*Population (estimated)* $n = 27751$
Sex and colour:		
White males	53 (26.2%)	8769 (31.6%)
White females	79 (39.1%)	14 121 (50.9%)
Non-white males	32 (15.8%)	2173 (7.8%)
Non-white females	38 (18.8%)	2689 (9.7%)
Age distribution:		
65–74 years	118 (58.4%)	17 154 (61.8%)
75–84 years	72 (35.7%)	8562 (30.9%)
85 years and over	12 (5.9%)	2035 (7.3%)
Diagnostic categories:		
Dementia	35 (17.3%)	2441 (8.8%)
Other mental disorders	59 (29.2%)	6270 (22.6%)
No mental disorder	108 (53.5%)	19 040 (68.6%)

TABLE III

Estimated population distribution of the two components of the social breakdown syndrome (SBS)

	Troublesome Behaviour			
Functional level	*Very*	*Moderate*	*Not*	*Total*
Low	0[d]	0[d]	0	0
Minimal	0[d]	48[c]	0	48
Almost adequate	108[c]	2490[c]	3419[b]	6017
Adequate	2712[c]	2832[b]	16 142[a]	21 686
Total	2820	5370	19 561	27 751

a = No SBS ($n = 16142$)
b = Moderate SBS ($n = 6251$)
c = Severe SBS ($n = 5358$)
d = Extreme SBS ($n = 0$)

unique number of individuals in the general population, allowing us to estimate the prevalence of psychiatric disorders and of the Social Breakdown Syndrome in the elderly population of the community.

Results

As Table II shows, our sample of 202 subjects was 42% male and 58% female (not importantly different from the estimated population). Non-whites accounted for 35% of the sample compared with 17.5% of the general population.

An examination of the age-distribution of the study sample compared with our estimates of the population did not reveal marked differences (Table II), but very few subjects over the age of 85 participated in any phase of the EBMHS, thereby limiting the statistical reliability of results. However, no better data have yet been published.

Each of the 202 subjects was assigned to one of three diagnostic categories (dementia/other mental disorder/no mental disorder) on the basis of information from the clinical reappraisal, except when he/she underwent a medical examination for the differential diagnosis of a dementia (suspected at clinical reappraisal), when the resulting diagnosis was used. Subjects with both dementia and another mental disorder were assigned to the 'dementia' category. The category 'other mental disorders' was composed primarily of alcohol problems, affective disorders, phobic disorders and personality disorders, occurring singly or in combination. The category 'no mental disorder' included persons with tobacco use disorder, uncomplicated bereavement and minor sexual disorders only. For a more complete description of the diagnostic process see Eaton *et al* (1981) and other papers still in preparation. Table II presents the distribution of diagnoses for the study sample and the estimated distribution in the population. The differences between the sample and the estimated population distribution are directly attributable to the EBMHS study design.

Our estimates of the population distribution of the two components of the Social Breakdown Syndrome (functional level and troublesome behaviour) are displayed in Table III. The present study did not identify any cases of the most extreme levels of SBS, and only a very small proportion of the total estimated population demonstrated minimal functioning with moderate troublesomeness. Most importantly, it appeared that almost the entire population functioned at an adequate or almost adequate level: all cases of severe SBS were attributable to moderately troublesome or very troublesome behaviour. Table IV displays the frequency of different levels of Social Breakdown Syndrome in the study sample and the estimated frequency in the general population.

Age is an important factor in the prevalence of Social Breakdown Syndrome and dementia. The estimated prevalence in different age-groups of SBS with and without dementia is shown in Table V. The prevalence of severe SBS is highest (41%) among those aged 85 or over. Severe SBS combined with dementia is also most frequent in the oldest age-group. However, the prevalence of severe SBS *without* dementia does not appear to increase dramatically with age.

Moderate SBS is most common in the 65–74 age-group, in which it is rarely associated with dementia. In fact, only a small fraction of the total burden of SBS in the community is associated with dementing disorders *except in the very old* (85 and over).

It is not surprising that dementia occurs without SBS in some cases, even among the oldest. This cross-sectional picture may capture developmentally differing stages of the condition.

Table V also displays the prevalence among males and females, white and non-white, of Social Breakdown Syndrome with and without dementia, and reveals extraordinary differences between sub-groups. Severe SBS is almost three times as common among non-white males as among white males, but this dissimilarity is not observed

TABLE IV

Sample distribution and estimated population distribution of different levels of the Social Breakdown Syndrome (SBS)

Degree of SBS	*Sample (n = 202)*	*Estimated population (n = 27 751)*
Severe	42 (20.8%)	5358 (19.3%)
Moderate	62 (30.7%)	6251 (22.5%)
None	98 (48.5%)	16 142 (58.2%)

among females. Moderate SBS is far more common in white males than in white females.

While almost two-thirds of white females in the estimated population display neither SBS nor dementia, only one-third of the non-white males are free of both conditions. However, since white females comprise an estimated 51% of the population and non-white males only 8%, the former group imposes the largest absolute burden on society in terms of SBS.

Diagnoses of mental disorder diagnoses and levels of Social Breakdown Syndrome were compared with the number of physical health problems reported by the informants. The inquiry about physical health was based on a short list of illnesses and conditions, including cancer, heart disease, high blood pressure, stroke and diabetes: Table VI should therefore be viewed with great caution because of the restricted list of health problems, the use of informants for such an inquiry, and the absence of any examination of the subject. We estimate that the majority of the population have one or more physical health problems.

Discussion

Although this study is unique in being population-based and using a standardised psychiatric examination, it must be re-emphasised that the sample is small. However, these data are the best presently available on the specific issues considered.

One of the striking findings in this cross-sectional study was that we found no examples of Social Breakdown Syndrome at its extreme (a combination of low functional level and very troublesome behaviour). There are several possible explanations:

1. Disability of such extremes may not be tolerated by helping networks in the community
2. Disability of such extremes may occur very infrequently in the community; it may be, in fact, primarily the product of institutional settings
3. The subjects with the most limited and troublesome behaviour may have dropped out before referral to The Helping Study, or refused to cooperate
4. Our informants may have failed to report the actual extent of the most embarrassing and disagreeable behaviour of their loved ones.

It is likely that each explanation is partially correct. For example, the interviewers and the first author contacted and attempted to enlist into the study a particular married couple: on the basis of a brief meeting and a visual inspection of their living

TABLE VI

Estimated prevalence of physical health problems among the elderly population with different degrees of the Social Breakdown Syndrome

Number of physical health problems	*Degree of SBS*		
	Nil	*Moderate*	*Severe*
None	4%	20%	30%
1–3	86%	65%	40%
4 or more	10%	15%	30%
	100%	*100%*	*100%*

TABLE V

Estimated population distribution of different degrees of SBS with/without dementia: (a) in different age-groups; (b) in males and females of different ethnic groups

	Age-group			*Whites*		*Non-whites*	
Degree of SBS ± dementia	*65–74 yrs (n = 17 154)*	*75–84 yrs (n = 8562)*	*85 yrs & over (n = 2035)*	*Males (n = 8769)*	*Females (n = 14 121)*	*Males (n = 2173)*	*Females (n = 2689)*
Severe SBS:	19%	16%	41%	11.4%	22.1%	32.8%	19.6%
Not demented	17%	14%	21%	7%	21%	19%	14%
Demented	2%	2%	20%	4%	1%	14%	5%

Demented	1%	5%	7%	1%	2%	9%	4%

quarters it appeared that they probably represented the 'Diogenes Syndrome' discussed by Clark & Mankikar (1975). Their home was filthy, rubbish-filled and fly-infested. The couple were unco-operative.

Our investigation points to a multiplicity of origins for the Social Breakdown Syndrome. It may be the net result of dementing disorders, other kinds of mental disorders, chronic and debilitating physical conditions, and perhaps particular personality configurations of hostility and withdrawal, and the interactions of these conditions and afflictions. However, the bulk of the community burden of Social Breakdown Syndrome is *not* associated with dementing disorders (only 15.2% of those with moderate or severe SBS were demented) or with other disorders, since 67.8% of those with moderate/severe SBS had no mental disorder (compared with 68.6% in the general population over 65). In fact, the proportion of persons with mental disorders other than dementia was lower among those with moderate/severe SBS (17%) than in the general population over 65 (22.6%). However, given that dementia was found in only 8.8% of the general population aged 65 or over but in 15.2% of those with moderate/severe SBS, it is clear that persons with dementing disorders do in fact contribute disproportionately to the community burden of functional failure and troublesome behaviour.

Both advanced age and physical health problems appear to be associated with SBS, but it seems quite possible that it is not age *per se* that is important in SBS but that age is a proxy variable for some unknown underlying diseases or conditions.

It appears paradoxical that 30% of those with severe SBS had no physical health problems. This group may have been comprised of persons with dementia or other mental disorders. Alternatively, this finding may be an artefact of our questions and methods and may in fact be misleading: other authors (Clark & Mankikar, 1975; Macmillan & Shaw, 1966) have noted that medical problems are frequent and important in self-care failures by elderly people. The Helping Study was not designed to collect detailed information about the role of physical health problems in the Social Breakdown Syndrome.

The differences in prevalence of moderate and severe SBS in whites and non-whites, males and females, are, at first glance, impressive. Non-white males appear to be most affected by SBS. However, these rates are estimates compiled from reports by informants; furthermore, family structures and living arrangements may explain part of the observed variations. For instance, older non-white men may tend to remain in the community rather than go into care because of the availability of extended family or protective living arrangements; alternatively, the barriers to admission to long-term care facilities may be slightly different for the various sex/colour sub-groups. Longitudinal follow-up studies and investigation of the frequency of SBS in patients admitted to long-term-care facilities are required to assist in unravelling the meaning of the observed differences in prevalence between sub-groups.

Conclusions

There have been many reports by clinical investigators of the enormous burden on families who care for the demented elderly. The implication has been that much of the community burden of care is attributable to dementing disorders. What has been demonstrated in this study is that most of the functional limitations and troublesome behaviour of elderly people in the community are unrelated to mental disorders. Analysis of Wave II of the Helping Study (12-month incidence data) may reveal other risk factors for the development, progression and resolution of the Social Breakdown Syndrome.

Nonetheless, persons with dementing disorders contribute disproportionately to the community burden of disability, demonstrating the epidemiological principle that observations in clinical settings may represent only the tip of an iceberg of unknown shape and size. This is a point that those delivering services to families of the elderly or planning services for the elderly should heed.

Acknowledgements

The ECA Program was a series of five investigations performed by research teams in collaboration with the National Institute of Mental Health (NIMH). The Helping Study was funded by the National Institute of Neurological and Communicative Disorders and Stroke and the NIMH. Thanks go to all who worked on The Helping Study, including D. Allen, J. Englund, L. Fillip, D. Haavik, Dr G. Lorenz, B. Harrison, M. Killilea, B. Sanders, Dr S. Wells, and the people of East Baltimore.

Appendix

The Social Breakdown Syndrome (SBS) has two components; poor functioning and troublesome behaviour. For our investigation of the SBS, we defined four levels of functioning and three categories of troublesome behaviour. The four levels of functioning were: *low/minimal/almost adequate/adequate*.

To be rated as *'low functional level'* the subject had to satisfy *all* the following negative criteria:

1. Subject did *no work* (i.e. no paid work; or work around the house or yard; or cleaning his/her room; or fixing things around the house; or doing the laundry)
2. Subject had *no productive hobbies* (gardening, sewing, knitting, woodwork, modelling)

3. Subject engaged in *no recreation* (visiting friends/relatives; going to church; going to sports events or clubs; using the telephone; watching TV; going to the movies; other recreations)
4. Subject *did not read or write*
5. Subject was *never left alone*

A subject meeting four of these five negative criteria was rated as *'almost adequate functional level'*.

To be rated as *'adequate functional level'*, the subject had to meet three criteria:

1. Subject did *some work* (as previously defined) OR engaged in a *productive hobby*
2. Subject engaged in *active recreation* OR *read or wrote*
3. Subject was *sometimes left alone*

The category *'minimal functional level'* was a residual category.

Behaviour was rated as *very troublesome/moderately troublesome/not troublesome*. It was rated as *'very troublesome'* if the subject fulfilled *any* of the following criteria:

1. Subject had to be physically restrained
2. Subject had to be urged and helped to eat
3. Subject needed help to get in and out of bed
4. Subject was incontinent
5. Subject was mute (did not speak for an entire day)
6. Subject harmed himself/herself or someone else, or self-injury had to be forcibly prevented

Behaviour was rated as *'moderately troublesome'* if *any* of the following criteria were met:

1. Subject had to be told to stay in one place, or needed restraining but was not restrained
2. Subject had to be helped to eat
3. Subject toileted in the wrong place, or needed help toileting at night
4. Subject spoke only when spoken to
5. Subject wanted to harm himself/herself but did not

Subjects whose behaviour did not satisfy any of the above criteria were classified as *'not troublesome'*.

The way in which different levels of functioning and different degrees of troublesome behaviour were considered together to give an overall rating of SBS (*nil/moderate/severe/extreme*) is indicated in Table III. Thus a subject functioning at an adequate level and exhibiting no troublesome behaviour was regarded as not suffering from SBS; moderate SBS corresponded to a combination of *either* adequate function with moderately troublesome behaviour *or* non-troublesome behaviour with 'almost adequate' functioning; and so on.

The following fictional examples indicate the types of problems and behaviour corresponding to different levels of functioning and different degrees of troublesome behaviour.

Example of adequate functioning

Mr J. is an 82-year-old man who cares for his demented 86-year-old sister. During the last week he has replaced a screen in the front door, cleaned the house a bit, tended his flower garden, gone to visit a neighbour, read the newspaper, and spent half of Saturday by himself while his niece took the demented sister to a dental appointment.

Example of low functional level

Miss J. is unable to do anything around the house or yard. She passes her days sitting on the couch and staring out of the window at passersby on the street. She is never left alone in the house.

Example of very troublesome behaviour

Mr S. is 72 years old and has no mental disorder. He is arthritic, almost blind, and has an amputation above the left knee. He has to be helped in and out of bed, cannot feed himself, and usually requires a bedpan twice during the night.

Quality of Life for 'New' Long-stay Psychiatric In-patients

The Effects of Moving to a Hostel

J. S. GIBBONS and J. P. BUTLER

We observed 15 'new' long-stay patients in wards in a District General Hospital Unit and a mental hospital, and again when they had lived for a year in a new hospital-hostel. There were significant changes in time spent in the community, social interaction, activity and abnormal behaviour. Residents believed they had more freedom and none wanted to return to wards. Six patients remained on wards. They showed no comparable changes and all wanted to live elsewhere.

It is now clear that a small number of adult psychiatric patients admitted to hospital will remain there for long periods, in spite of active treatment and rehabilitation. In England, for every 100 000 of the general population aged 15–64, between 24 and 36 adults in 1979 were likely to be newly recruited long-stay psychiatric patients (Jennings, 1983). A national survey of such patients found that most could not look after themselves, and were not acceptable to local authorities or voluntary bodies providing accommodation, because of their multiple handicaps and high levels of psychotic and difficult behaviour (Mann & Cree, 1976). These patients are not a homogeneous group: in this paper we are concerned only with those under 65, who were admitted to hospital from one health district between 1979 and 1983, stayed for at least a year, and did not have multiple handicaps that required care in psychogeriatric or other special units.

Such patients are now cared for in long-stay mental hospital wards; or in District General Hospital (DGH) units; or in new hospital–hostels, which are intended to provide continuing treatment and 24-hour nursing care, but in a more domestic and less institutional setting (DHSS, 1975). Evaluative studies suggest that patients living in hospital–hostels show more behavioural improvement than patients living in hospital wards (Wykes, 1982; Gibbons, 1986). But the new hospital–hostels are also intended to provide a better quality of life than can be offered by either the old long-stay wards or the new DGH units. This paper evaluates the extent to which patients' quality of life improved when they moved from hospital wards to a new hospital–hostel.

Measurement of environment

In the pioneering study by Townsend (1962) of old people's homes, a series of items describing such features as the building, access to possessions and staff attitudes made up a quantitative scale which could be used to evaluate and compare quality of care in different institutions. Jones & Fowles (1984) point out

> the difficulty, as with all such scales, is that it is necessary to defend both the choice of items and the weighting accorded to them; and when this is done what appears to be an objective and reliable and reliable measurement often turns out to be both subjective and unreliable.

Moos (1974), within a theoretical framework of social ecology, developed a Ward Atmosphere Scale to measure perceived organisational climate. The numerous items had to be rated independently by staff and patients, and compliance was low on chronic wards. The scales were not designed to measure patients' quality of life. For these reasons the WAS was not suitable for our purposes.

The more management practices in institutions are characterised by rigid routines, regimentation of individuals into groups and social distance between staff and inmates, the more an institution approaches the 'total' model of Goffman (1961). King *et al* (1971), in a study of management practices in residential institutions for children, assumed that the less 'institution-orientated' regimes were the more desirable. Although they did not have independent measures of outcome, 'restrictive' management practices have been associated with undesirable outcomes (Apte, 1968). Restrictiveness, as measured by the Hospital/Hostel Practices Profile, was much more marked in hospital wards than in a new hospital–hostel (Wykes, 1982). Hewett (1979) criticised this measure as an index of quality of life, suggesting that many of its so-called 'restrictive' practices were in fact 'caring' and necessarily protective in relation to the needs of severely handicapped residents. The measure had the further disadvantage, for our purposes, that it was derived entirely from the perceptions of a senior staff member.

The principle of *normalisation* – 'making available to the mentally retarded patterns and conditions of everyday life which are as close as possible to the norms and patterns of the mainstream of society' (Nirje, 1967) – also appeared relevant to our attempt to assess the experiences of mentally ill people in different residential environments. Normalisation does not imply 'dumping people into communities from institutions without support', but rather the creation of 'highly specialised support services and clinical/technical expertise which can be used to help people achieve greater degrees of independence.' In judging the quality of a particular residential service, account is taken of how far its regime conforms to the principle of normalisation in a number of specific areas (Pieper & Cappuccilli, 1980).

We wished to describe the impact of different regimes upon residents and obtain their own views of their experience. A recent survey of Los Angeles board-and-care homes showed that three-quarters of mentally disabled respondents were able to take part in structured interviews about their quality of life (Lehman, 1983). This contrasted with the difficulty residents in the Maudsley hospital–hostel had had in answering simple yes/no questions. We therefore decided to gather data by a combination of direct observation and semi-structured interviews with residents. We assessed their quality of life on hospital wards and after moving to a hospital–hostel along the following dimensions:

(a) integration: nature and site of building; amount of time spent in community; contact with relatives and friends
(b) living situation: space; privacy and quiet; security; freedom; social relations
(c) finances: weekly income
(d) activity: time spent on work activity; time spent doing nothing; inappropriate behaviour
(e) satisfaction with accommodation.

The settings

The three residential treatment settings are described below.

The first setting was long-stay wards in the mental hospital (MH wards). The mental hospital dated from the nineteenth century and stood in spacious grounds 12 miles from the city. The long-stay wards to its rear were typically institutional in design. When the research began in 1983 there were two high-dependency single-sex wards with a ratio of two nurses to every three patients, the remaining wards being mixed-sex, with lower staff-patient ratios. By 1985 the hospital had changed. It was scheduled to close in a decade; many 'old' long-stay patients had been moved out to low-dependency hostels or private care, and the remaining wards reorganised with more rehabilitative aims. There were less than two nurses to every three patients.

The second setting was a rehabilitation ward on an upper floor in the DGH unit. The unit opened in 1979 and took all admissions from the catchment area. It was a purpose-built 95-bedded unit next to a general hospital and near the city centre, in an area with a reputation for social problems. It had no grounds and space was at a premium. The rehabilitation ward provided a 3-month programme for most of its 20 inmates, the rest following a slower pace; all, however, had some planned programme. There were 18 nursing staff for the 20 patients, and higher medical coverage than in the MH wards.

The third setting was the new hospital–hostel opened in January 1984 to provide for the district's long-stay. It was in two converted, linked houses on four floors, approximately 5 minutes' walk from the DGH unit across a busy main road. It had 20 places, with 20 nursing staff. Medical cover was provided by a consultant and senior registrar, and there was a part-time psychologist and occupational therapists. The staffing ratio was only slightly better than in the DGH ward but very much better than the MH wards, and was approximately twice that recommended for the highest dependency group (the elderly mentally infirm) in voluntary residential care by a DHSS working party (Avebury, 1984). The building was not marked as an institution and did not stand out from the neighbouring small hotels and blocks of flats. It shared with the DGH ward the advantages and disadvantages of its position near the city centre. As in that ward, the aims were rehabilitative, though the pace was slower and it was recognised that many residents would never live independently. Every resident had a nursing plan, in some cases fairly precise, specifying goals and tasks, but in other cases merely prescribing a general nursing regime. The hostel staff consciously tried to create a warm, informal climate and to avoid institutional routines and foster independence to a greater extent than was possible in the hospital wards. The hostel also differed from the DGH ward in its domestic scale and furnishings and the additional space provided by a large garden.

TABLE I
Patients admitted 1979–1983 who remained in hospital for at least a year: status at September 1985

					Hospital first diagnosis

Dead	5	56.6	4	13.0	1	2	2
Total	42	44.5	25	8.7	19	8	15

The patients

The sample consisted of all residents who had lived in the new hospital–hostel for a mean of 15 months (11–18) by August 1985. There were 15. All had been studied previously, when they had been continuously on hospital wards for a year. Table I shows their characteristics in comparison with those of all the patients under 65 admitted from the catchment area 1979–1983, and staying in hospital for over a year. Of the 42 identified cases, 12 had been discharged before August 1985 (two from the hostel to less sheltered settings) and five had died. Four cases were excluded (primary organic conditions needing nursing in special units). Thus 21 cases were 'eligible' for the hostel, of whom 15 had been accepted into it. Eleven of these had moved to the hostel from the DGH ward and four from the MH wards.

Method

We used the Behaviour Observation Instrument (Alevizos *et al*, 1978) to study sample patients on the wards and after they had lived in the hostel for 11–18 months (residents moved in at different times). During July 1983 and 1984 and August 1985 we observed in daily shifts from Monday to Saturday. A shift was 09:00 to 13:00; 13:00 to 17:00; or 17:00 to 21:00. Within the shift we observed all patients at approximately hourly intervals in a random order. The observer needed a brief training to become familiar with the instrument's categories. She had to watch the patient unobtrusively for 5 s and then withdraw to code the observed behaviour on to a schedule, with a brief description. When subjects could not be found on hospital property the observer tracked them to local destinations, such as a cafe, shop or the League of Friends, where they could be observed unobtrusively from the street. When subjects were out on longer trips during observation periods, the observer established their whereabouts by questioning staff and checking with the subjects themselves on their return. When patients' whereabouts could not be established, or they were known to be in another hospital, observations for that period were omitted. In 1983 the authors carried out 19 observations on each patient independently but simultaneously. Inter-rater reliability was 97% and a similar level of agreement was reached in reliability exercises in 1984 and 1985.

For the analysis a notional weekday was created consisting of the 12 hours from 09:00 to 21:00. Three observations for each hour, taken on different days, were drawn, making 36 total observations during a weekday for each case. The same procedure was used for Saturday, except that the notional day lasted from 09:00 to 17:00. We also observed patients' material circumstances of life in wards and in the hostel.

In 1985, at the end of the research, 14 of the 15 patients completed a semi-structured interview about their own perceptions of quality of life. One patient could answer only a few questions. The questionnaire items were derived from areas considered important in the literature on normalisation and from preliminary unstructured observations made by the senior author. She visited the living room to engage residents in conversations about aspects of hostel life that were important to them. No pilot interviews were carried out. Sample questions are shown in Appendix 1.

Results

Integration

The building

The mental hospital was the least 'normalising' setting, clearly marked out as a segregated institution and without easy access to community resources. The DGH unit was in the city, giving easier access, but equally institutional in appearance and reputation. The hostel was the most normalising, sharing the DGH unit's easy access but without its distinguishing institutional symbols. However, with its 20 places it was too large for residents to be easily assimilated into a local community, and they were 'patients' in a treatment setting, without the rights of tenure enjoyed by other citizens.

Amount of time in the community

Table II shows that as patients had used space differently in the MH and DGH wards, their pattern of change on moving to the hotel also differed. Former MH patients spent significantly less time in occupational therapy and more time in the community after moving. Former DGH patients spent significantly less time in bed, less time in corridors and

Table II

Use of space in wards and hostel: weekdays

hallways and more time in living rooms. They increased the proportion of time they spent in the community, but not to a significant extent: they had already been spending greater periods of time outside hospital property when they were in the DGH unit.

On Saturdays MH patients went out more (18% of the time) and increased this further, though not to a significant extent, after they moved to the hostel. In the DGH unit and the hostel the use of space was much the same on Saturdays as it was on weekdays. In the mental hospital distance, expense and the structured weekday apparently combined to prevent short trips out from hospital property, so there was a dramatic increase in time spent in the community after the move to the hostel.

We examined the extent to which patients' time in the community was organised by others: by the hospital in the form of organised recreation or trips with a member of staff; and by relatives in the form of arranged home visits. Patients in the mental hospital made no trips into the community on their own initiative, but when they were in the hostel 86% of their time outside was self-initiated. In the DGH unit patients were able to go into the community of their own accord, and they maintained much the same pattern in the hostel.

Hostel residents went out to obtain goods and services that previously had been available within the hospital. Instead of going to the hospital shop or the leisure centre they went to the local newsagents, food shops and café. Some went out to the hairdresser instead of being visited by her in hospital. They went for walks in the town centre or on the local common and made use of the local cinema and pubs. Some residents visited friends, who were usually also former patients. There were occasional problems when hostel residents paid unplanned and unwanted visits home.

Altogether, hostel residents increased their time in the community from 9% to 15%. Nine of the 15 spent more time in the community.

Contact with relatives and friends

The move to the hostel made little difference to the pattern of contact with relatives. Four of the 15 had no contacts with any relatives, two expressing regret: 'My whole family have all gone away'. 'My sibling ones, my senior ones all gone away.' Seven exchanged visits with relatives at least weekly; the remainder saw relatives several times a month. Six out of 15 wanted to spend more time with relatives but most were satisfied. Seven out of 15 were visited by friends outside hospital and/or went to visit them. In most cases, but not always, these were friends made in hospital who were now in the community. The move to the hostel did not result in residents seeing more of their families, but at least two stopped absconding home, which had caused distress when they were in hospital.

Living situation

Space

Four residents had had small single rooms on the wards at baseline; the rest had been in dormitories. In the hostel only one had a single room, three were together and the rest in double rooms. The bedrooms were all large and pleasantly furnished. Only one person complained of insufficient space in the bedroom, but four thought the hostel's leisure space was insufficient, compared with the wards, or complained of competition for scarce space: 'The staff claim the green room so we cannot use it.' The hostel had a dining room, a small lounge/TV room and two other small leisure rooms as well as the garden. The basement space was unattractive to residents and seldom used. To an observer the leisure space appeared cramped and noisy when residents were together, although it was on a more domestic scale than in the wards.

Privacy and quiet

Only three residents complained of insufficient privacy in the hostel as compared to the wards. Most did not want to be alone: 'I don't see any point in being alone. It wouldn't be a good idea to be able to lock the bedroom door.' Residents had various strategies for finding privacy and quiet when they needed it, the commonest being to go to their rooms while their roomate was elsewhere or to go out: 'I like solitude. I find it on my bicycle.' Six mentioned that it was sometimes too noisy in the living room.

Security

All residents had lockable wardrobes and chests for their personal possessions, as they had had on the wards. The majority expressed no fears for their own safety or that of their belongings, but three mentioned violent episodes and five mentioned thefts or losses. In general residents felt safer in the hostel: 'I have a lock to my chest of drawers and I keep the key with me. At [mental hospital] the key would be taken from me if I fell asleep.'

Freedom

We examined restrictiveness in relation to rules about getting up and going to bed; access to kitchen and laundry facilities and leaving the building. On the wards there were rules about getting up and going to bed, which were operated more firmly in the mental hospital. In the hostel 14 out of 15 believed they could get up and go to bed when they liked: 'Sometimes I feel so tired I stay in bed all day.' In MH wards laundry was done centrally, but patients had had access to a washing machine in the DGH ward and most had done some of their own washing. In the hostel all residents had free access to the laundry room. Five managed all their own washing, the rest getting some assistance from staff. On the wards none had free access to the kitchen. In the hostel all residents breakfasted at their own time in the kitchen, washing up their own things. But residents disagreed over whether there was free access to the kitchen at other times, six believing there was not: 'I can use it but not wander in as I want.' 'You can use the kitchen if you ask. Our kettle got burnt out because somebody didn't turn if off so you can understand.' Access to the kitchen was free in theory but limited in practice because of staff concern about risk and using up supplies. All residents believed they could go in and out of the building as they liked: 'You can go out without saying, but advice is to tell staff so they can save a meal.' This was little different from the rules on the wards, but individual patients had been more restricted there, notably by being kept in pyjamas in the MH wards to prevent unauthorised journeys.

Social relations

We first examined the proportion of time patients spent in talking, or being talked to, in the different settings. The proportion of time spent in talk increased from 18% on the wards to 34% in the hostel – a difference that would have happened by chance less than 1 in 1000 times. The increase was similar for former MH and DGH residents.

We next examined whether interaction differed qualitatively: in the people chosen, or the topics of discussion. In both wards and hostel 59% of interactions observed were with staff. In the hostel there was a slight increase in the proportion of observed interactions with visitors (10% *vs* 6%), at the expense of those with other patients. Table III shows the topics with which observed interactions were concerned. On the wards, 21% of the patients' observed talk with staff had been related to cigarettes. After a year in the hostel this proportion fell to 4%, while the proportion of more general conversational interchanges with staff rose. On the other hand, the proportion of patient-to-patient talk about cigarettes increased after the move to the hostel, though the difference was not significant. On the wards, staff rationed the supplies of some patients, thus forcing them into conversation to ask for cigarettes. In the hostel, staff did not control the cigarettes, so that when residents ran out they had to bargain with each other. The proportion of observations when patients were actually smoking did not rise significantly in the hostel, so that staff control of supplies did not seem an effective way of reducing smoking.

TABLE III

Reasons for observed social interactions in wards and hostel (n = 15)

Total observations (audible interactions)	52	115	28	60

**χ^2 9.81 $P<0.01$.

In interview nine residents expressed positive feelings about staff, with four critical and two not answering. Most expressed positive feelings for other residents. However, in spite of this and their increased social interaction, three-quarters said they were often or sometimes lonely: 'I feel isolated, I've no idea why. It's not because people don't want to be friendly.' 'Lonely, yes, but there's nothing to say to anyone.' 'I should pay someone to talk to me.'

Finance

The move to the hostel had not affected the poverty of most residents. Nine still had an income of less than £10 a week, derived from social security and small 'incentive payments' for doing hostel jobs. One man did odd jobs for a florist for £1 a week: no others had any outside paid work. For five, income was brought above £10 by inheritance or pension rights.

Activity

Residents spent significantly less time doing nothing at all after they moved to the hostel as compared with both MH and DGH wards (Table IV). Although, as we have seen, they no longer attended occupational therapy, they spent as much time as before on 'work' activities. (However, this was a good deal less than the time spent at 'work' in the Maudsley hospital–hostel.) In the hostel, 'work' activities were more individualised and closely related to residents' real-life roles: for example, going shopping or practising cooking individually with the occupational therapist, doing housework or jobs in the garden. We never observed residents in the simulated mass-production activities of some occupational therapy in the hospital.

In the hostel, residents also spent more time on self-care and at meals. This was due to change in former DGH ward residents. Meals there had involved queueing for some time under supervision in a corridor to enter the canteen: patients

TABLE IV
Activity in wards and hostel (n = 15)

1. Calculated estimates from the time-budget of residents in the Maudsley Hospital–Hostel (Wykes, 1982).
2. Attending meeting, receiving medication, conversation unaccompanied by other activity, other.
3. Sitting, standing, lying down, performing no activity other than smoking.

sometimes skipped meals, at which there was little or no conversation. Meals in the hostel were served by the cook in a much more domestic and sociable atmosphere, and residents' behaviour changed accordingly.

The occurrence of inappropriate social behaviour may be taken as an index of tension and so indirectly of quality of life. On the wards patients had been rated (on the observation instrument's standard definitions) as behaving abnormally 12% of the time. In the hostel there was a significant decline to 6%.

Satisfaction with accommodation

We asked residents to tell us three good and three bad things about the hostel. The most commonly mentioned good things concerned greater freedom, the hostel's central position; and its facilities: 'Not so many rules and regulations. Don't have to call staff Mr or Mrs so-and-so.' 'It's easy to go out and do what you want to do.' 'Freedom, not as strict.' 'Easy to go out in the garden. Can do cookery or art.' 'Going on the minibus.' 'Food'. Ten residents mentioned something they did not like about the hostel. Four complained about other residents: 'Some get on my nerves a bit.' Four wanted more food/cigarettes. One did not like sleeping alone. One wanted more freedom: 'I'd like it more if I was paying my way more.' We also asked where residents would prefer to live if they could have a free choice. None wanted to return to hospital wards. Six nominated the hostel as their ideal accommodation; three wanted to live independently in their own house; three wanted to live with parents; one in another hostel; one in a hotel; and one 'in the country'.

Cases who remained on wards

We observed the six patients rejected for the hostel at baseline and follow-up periods, and we also interviewed them in the same way about their quality of life. These rejected cases were less withdrawn and more active and aggressive than cases accepted into the hostel (Gibbons, 1986). Table V shows that, in contrast to the hostel residents, those remaining on wards spent less time in the community and more time doing nothing; they hardly increased their social interaction.

The patients left in wards expressed less satisfaction in interview. Four complained of noise and lack of privacy: 'I can hear people arguing, shouting, walking, closing the door, how they go to bed. You don't even get much peace in the living room. Its a bit quieter where I sit [in the corridor].' Five of the six expressed fears of other patients and thought their property was not safe. All said they were lonely, although four saw relatives regularly. There were more rules: none could use the kitchen; all but one believed

TABLE V
Observational indices of quality of life: change in 15 patients who moved to hostel and six who stayed in wards

	Baseline *Movers*	*Baseline* *Rejected*[1]	*Follow-up* *Movers*	*Follow-up* *Rejected*[1]	*Number of individuals who improved* *Movers*	*Number of individuals who improved* *Rejected*
In community[2]: % of time	9	16	15	6	9*	1
In social interaction: % of time	18	21	34	25	13**	3
In 'work': % of time	8	17	8	9	7	1
Doing nothing: % of time	46	22	27	24	12**	1
Behaving inappropriately: % of time	12	3	6	1	9*	1

1. All rejected cases were studied at baseline in 1983 and at follow-up in 1985.
2. The fall in time spent in the community for the movers is mainly due to a change in one case, who was in the DGH unit at baseline but had been moved to the mental hospital at follow-up.

McNemar Test for Significance of Change: *$P<0.05$; **$P<0.01$.

they could not get up and go to bed when they liked; two believed they could not go out freely.

None wanted to go on living in a hospital ward; two said they wanted to move to a hostel; three wanted their own home or family; and one did not answer.

Discussion

We conclude that while the hospital–hostel provided a better quality of life on the majority of the indices we devised, its large size meant that it was somewhat overcrowded and noisy. It did not provide single rooms, considered to be highly desirable in the government's code of practice for residential care, though its residents did not complain about this. It was probably unreasonable to expect that residents' income could be improved in it, and this did not happen. The hostel residents went into the community more, and made more use of its resources, but subjectively the majority felt lonely and cut off, and those who lacked contact with relatives and friends did not increase it after moving. As yet no voluntary visitors or groups were involved; this might have facilitated a different kind of integration into the community. The main changes were in residents' increased feelings of freedom, their higher level of activity – even though staff were tolerating longer hours in bed – and a change in the amount and quality of their social interaction.

The hostel's geographical situation and staff/patient ratio did not account for the improved quality of life, except on the one measure of time spent in the community. The difference on this between cases from mental hospital and DGH unit suggested that once barriers of distance are removed, most patients find it quite natural to use ordinary community resources for their own needs. But the DGH ward and the hostel had the same geographical position and a very similar staffing ratio. Therefore, the significant changes in the activity and social interaction of former DGH ward patients were due to other causes. The most likely were the greater freedom, flexibility and informality of the hostel regime, mentioned by its residents in our interviews.

These findings, particularly on social interaction, are consistent with those from other studies of people who have moved from large institutions to smaller, more domestic units (Garety & Morris, 1984; Hemming *et al*, 1981; MacEachron, 1983). We would argue that it is worth paying a higher price for each place in a hospital–hostel than in a long-stay ward in order to obtain a better quality of life. However, future experiments might show that equally good results could be obtained in hostels with somewhat fewer professional staff and more links with voluntary groups; or even in a range of carefully planned, well supported domestic settings.

Acknowledgements

We thank Professor J. L. Gibbons, Dr B. Morris, Dr B. Barraclough, Dr B. Steinberg and the nurses and residents. The study was funded by the Southampton and S.W. Hampshire Health District.

Appendix 1

Residents' questionnaire: sample questions

Overcrowding

Probes: Do you have enough space in the bedroom?
Enough space for storing your belongings?
What about the dining room?
Is there enough space for leisure activities?

Privacy

Probes: Can you be by yourself if you want?
Can you be behind a locked door if you want?
What do you do if you want to be alone?

Danger to self

Probes: Are people threatening/violent?
Do you feel nervous/frightened of some people?
Has anyone hurt you?

Danger to belongings

Probes: Do you feel property is safe here?
Have you lost any property?

Loneliness

Probes: Have you got anyone you can really talk to?
Do you feel lonely?
Have you got any friends (details)?

Freedom

Probes: Can you use the kitchen as you please?
Can you go out when you want to?
Can you get up/go to bed when you want to?

Ideal accommodation

Probes: If you could live wherever you liked, where would you choose?
e.g. – Hospital ward (named hospital)
– Hostel
– Group home
– With family
– On your own
– Somewhere else.

Can Categorical and Dimensional Views of Psychiatric Illness be Distinguished?

D. A. GRAYSON

Bimodality in a distribution of symptoms is often claimed to be convincing evidence that a disorder is categorical, a discrete disease entity, rather than the extreme on a continuous dimension. However, using concepts from contemporary psychometric theory it is shown that bimodality can arise from the dimensional viewpoint. In fact, contrary to the usual belief, bimodality would be expected to occur in many research contexts if the dimensional alternative were correct.

In recent psychiatric research, debate has arisen as to whether certain disorders are categorical or dimensional. For example, in depression there is debate about the binary or bipolar nature of the illness (Garside & Roth, 1978; Kendell & Gourlay, 1970*a*). One unchallenged principle is that the existence of discrete disease entities is confirmed when a linear function of scores on a symptom inventory shows bimodality. Moreover, such data are believed to be inconsistent with the opposing dimensional view (Moran, 1966). Indeed, the point is made by Fleiss (1972), Everitt (1981) and Garside & Roth (1978) that such bimodality is a sufficient, but not necessary, indicator of disease categories. The implication of this is that the demonstration of mild bimodality, or even just skew, is enough for an underlying categorical illness to be inferred. For instance, Cloninger *et al* (1985) cite, as evidence in favour of categories, the results of 'admixture analysis' showing that two normals are better than one in fitting a discriminant function distribution.

Few would argue with the description given by Kendell (1975) of the conceptual linkage from a categorical illness to bimodality. But before one makes the reverse inference from bimodality to a categorical illness, there is a fundamental obligation to show that such bimodality cannot arise from a dimensional illness. Ruling out this latter alternative has not received appropriate attention.

Everitt (1981) states what is probably a widely held belief:

> Now for a *population* frequency curve, bimodality is (except in pathological cases) a sufficient (although not a necessary) condition for the presence of subtypes and certainly if, in a fairly large sample, bimodality appeared no matter how the data were arranged, it would be pedantic to insist it might be an artefact.

Garside & Roth (1978) provide a more substantial argument for believing bimodality is inconsistent with a dimensional illness. In discussing bimodality of a linear discriminant function score, they state:

> If a significantly non-unimodal distribution is then obtained, it seems safe to reject the hypothesis that the population distribution is unimodal, and to conclude that distinct groups of patients exist.

This conclusion is supported by an earlier statement to the effect that the central limit theorem entails unimodality in the sum of a number of (almost) uncorrelated (0, 1) variables. However, to infer distinct groups, and not a dimensional illness, requires the truth of a premiss suppressed in their reasoning: it must be true that a dimensional illness will yield data wherein pairs of symptoms show little or no correlation.

This premiss is in fact false, and the main thesis of this paper is that symptom–symptom correlations yielding bimodality can arise from a dimensional illness, and that such a state of affairs is far from being a 'pathological' case, as has hitherto been assumed.

The paper is divided into three major sections. The first demonstrates how bimodality can arise from a dimensional illness and exhibits similarities in the way symptom inventory data may arise from either dimensional or categorical illnesses. The second section discusses research biases which tend to ensure that dimensional and categorical illness will be indistinguishable. The final section deals with the implications of these issues.

From here on it is assumed that the bimodality under discussion arises from a symptom inventory of dichotomous symptoms scored 1 or Yes in the direction of illness. It is further assumed that the score at issue is the simple sum of endorsed symptoms. These simplifications are made in the interest of clarity, and the points made below readily generalise to weighted symptoms sums and finer symptom scoring than (0, 1).

Bimodality with dimensional illnesses

This section explains Latent Trait models (contemporary psychometric accounts of questionnaire data assuming a latent dimension) and presents distributions of the symptom sum that explore the conditions under which a dimensional illness will yield bimodality. The close conceptual similarity between such dimensional models and disease entity models is examined.

Latent Trait model

The main applications of the Latent Trait theory are in aptitude-testing (Rasch, 1960; Birnbaum, 1968; Lord, 1980), and the theory seeks to account for questionnaire data in terms of a single latent dimension and aspects of the individual items. If one equates the items with symptoms and regards the questionnaire as an inventory relating to an underlying dimension of illness severity, then the theory is quite appropriate in psychiatric contexts. Such applications are now appearing in the literature (Gibbons *et al*, 1985; Duncan-Jones *et al*, 1986; Grayson, 1986).

The model usually assumes that the population takes a standard normal distribution (mean zero, unit variance) on the underlying illness dimension. Those with positive scores are 'sicker' than those with negative scores. The remaining feature of the model attempts to capture how the individual symptoms relate to this latent illness dimension. Generally it is assumed, for each symptom, that probability of endorsement is an increasing function of illness severity only. The higher a subject is on the illness dimension, the greater his probability of endorsing a given symptom. This assumption is very general, and in applications the symptom functions are given explicit functional form.

Figure 1 represents such a structure. On the x-axis the value on the latent dimension is plotted. The lower graph shows, inverted, the normal distribution of subjects on this dimension, and the upper graph shows, for a given symptom, the function relating endorsement probability to the value on the latent dimension. Subjects higher on the dimension ('sicker') have higher probability of symptom endorsement. This particular symptom function has the 2-parameter logistic representation. If $P_j(z)$ is the probability of symptom j endorsement for a subject of illness dimension value z, then

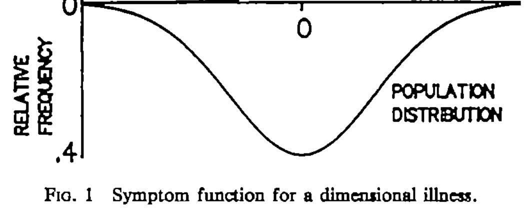

FIG. 1 Symptom function for a dimensional illness.

$$P_j(z) = \frac{\exp\,[s_j(z-t_j)]}{1+\exp\,[s_j(z-t_j)]}$$

or

$$\log\left(\frac{P_j(z)}{1-P_j(z)}\right) = s_j(z-t_j)$$

The expression is characterised by two parameters, s_j and t_j. When $z=t_j$, $P_j(z)=0.5$. So t_j is the value of the illness dimension that yields a 50% chance of endorsing symptom j. It is called the 'threshold' of the symptom, and serves to locate the symptom at a particular place on the illness dimension. This logistic curve rises slowly from the left, has maximum slope at $z=t_j$, and flattens out above this value. The slope at $z=t_j$ is $s_j/4$, *and the* s_j parameter is called the 'slope'. The larger the s_j value, the better the symptom is discriminating at threshold, where it must discriminate maximally. The symptom in Fig. 1 has a threshold at $t_j=1.0$ and a slope of $s_j=2.0$, indicating that it is discriminating well among moderately sick (positive z) subjects, but not among the well or the extremely sick.

Dynamics of dimensional bimodality

By choosing a number of symptoms with particular (s_j, t_j) combinations, it is possible to generate the data arising from application of a symptom inventory to a dimensional illness, and thus to investigate the conditions under which bimodality occurs. Such theoretical distributions are presented in Tables I–III.

Table I shows the distributions of this number-endorsed score for a variety of inventories applied to a normally distributed latent dimensional illness. In each inventory all symptoms are identical, with $t_j=0$ and s_j as indicated in the table. The number of symptoms in the inventory is also specified ($n=6$ or $n=23$). The slopes range from 16 to 1.9.

In all these examples, distinct bimodality occurs. The dynamics of this effect seem clear. All symptoms are located in the middle of the population ($t_j=0$). Thus, the bulk of the subjects low on the dimension rarely endorse many symptoms, and the bulk of those high on the dimension rarely fail to endorse many symptoms. This is more so for steeper slopes. Thus over intermediate patterns of symptoms there is a preponderance of all-zero or all-one patterns of responses, and hence bimodality in the distribution. So two conditions jointly yielding dimensional bimodality are coincident symptom thresholds and moderate to steep slopes. In other words, the symptoms must be discriminating well at a similar level of illness severity.

Examples in Table II show that the bimodality is surprisingly robust. The twelve-symptom inventory consists

	12	136	86	70	63	59	57	57	57	59	63	70	86	136

of two six-symptom inventories combined, and both these inventories consist of symptoms with (s_j, t_j) combinations (4, 0), (4, 0), (4, 0.2), (4, −0.2), (1.7, 1.2), (1.7, −1.2). The total proportions endorsing the symptoms are 0.5, 0.5, 0.43, 0.57, 0.2 and 0.8, respectively. The first, third and fifth symptoms have thresholds lying at the 50th, 58th and 88th population percentiles, respectively. The fifth and sixth symptoms, at either extreme, have the effect of ensuring that few subjects at the well extreme and few subjects at the sick extreme obtain inventory patterns of all zeros or all ones respectively. Thus the distribution is bimodal with two 'humps' rather than U-shaped.

All the distributions in Table III were generated with symptoms having a common slope of 3.0. The six-symptom inventories were constructed from three such symptoms with given thresholds and three with the same, but negative thresholds. The twelve-symptom inventories, again, are two six-symptom inventories combined. Removing the extreme items restores the more extreme U-shape bimodality.

All these examples demonstrate that a dimensional illness can produce bimodality, and together they provide insight into how this occurs. The conditions seem to be that the symptoms all perform their best discrimination round about the same place on the latent dimension. In terms of the

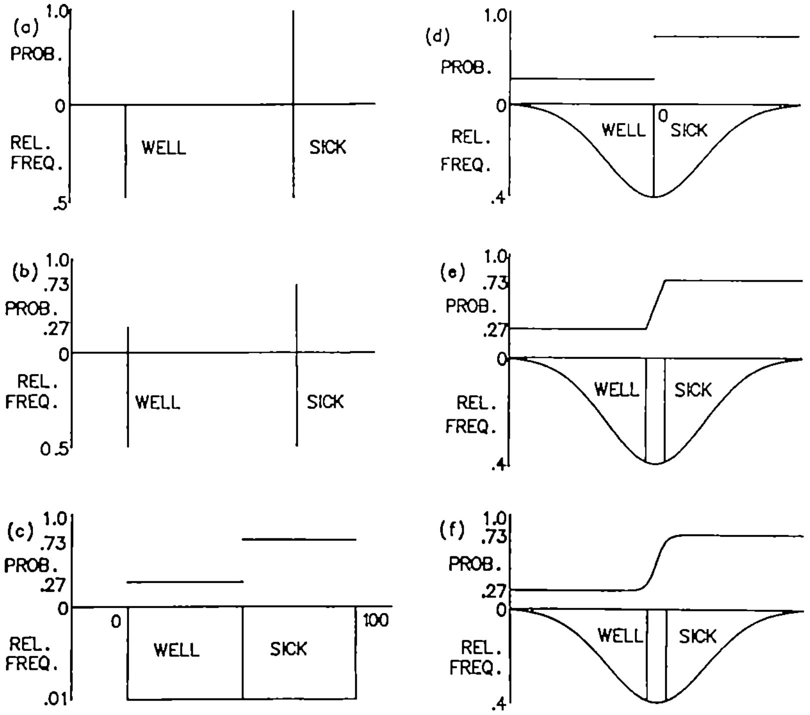

Fig. 2 Symptom function for a categorical illness.

symptom functions used here, the thresholds of a majority of symptoms must cluster about a common region on the illness dimension, making the population appear as two groups in the inventory data.

Similarity of data from dimensional and categorical illnesses

The data from a symptom inventory consist of frequencies of the possible patterns of ones and zeros across the inventory. These in turn depend on the relationship between each symptom and the underlying illness. If the responses to a given symptom can be shown, in principle, to be produced in much the same way from either type of illness, then it is, in principle, impossible to discriminate categorical from dimensional illness using data from a symptom inventory.

Part (a) of Fig. 2 represents the ideal relationship between a symptom and a categorical illness (with prevalence of 0.5 in the study population). Sick subjects, and only sick subjects, endorse the symptom. This is ideal, and an inventory of such symptoms would yield response patterns consisting of all zeros (the well group) and all ones (the sick), and nothing intermediate.

Two ways in which this unrealistic ideal might be realistically degraded are as follows. The first is by allowing the symptoms to be less than perfectly reliable. The second is by allowing the illness to be less than perfectly categorical; that is, having some subjects intermediate between well and sick. In accordance with the concepts of Kendell (1975), such subjects should be relatively infrequent.

Part (b) of Fig. 2 shows a symptom which is not perfectly reliable. Sick subjects have 0.73 probability of endorsing the symptom, well subjects 0.27. Part (c) is another way of representing Part (b), but along an artificially constructed dimension instead of illness categories. The well group is aligned fully to the left of the sick group. Within each group the subjects are ordered randomly. To each subject one can assign a percentile score reflecting the percentage of the total population to the left of that subject. Thus, well subjects will have percentile scores of 50 or less, and the sick will have greater than 50. A given subject still retains the same symptom probability as in part (b). Expressing the mechanism giving rise to symptom data in this way is theoretically fully equivalent to that in part (b), even if artificial.

Part (d) of the figure takes the representation one step further, but is still equivalent to the two earlier representations. To each subject is assigned the z-score associated with that subject's arbitrary percentile score (obtained by using tables of a standard normal variate). The symptom's relationship to the two categories is now shown as a symptom function over a score which is normally distributed in the study population, albeit a 'score' with no empirical interpretation.

Next, the assumption of less than perfectly distinct categories is incorporated by imposing a small 'grey area' between the sick and well groups. Sick subjects still have 0.73 probability of symptom endorsement, well subjects 0.27, and intermediate subjects have intermediate symptom-endorsment probability, as in part (e) of the figure.

Finally, if we allow the reasonable possibility that within either the well or sick groups, symptom-endorsement probability is not totally homogeneous, part (f) results.

Comparison of part (f) with Fig. 1 reveals the close conceptual similarity between the mechanisms generating symptom inventory data in categorical and dimensional models of illness. It is this close similarity which, in principle, ensures that discrimination between the two views, using inventory data, will be difficult.

A categorical illness differs, in general, from a dimensional one for two reasons:

(a) If the subjects in the 'grey area' are infrequent, then the symptom functions must rise steeply above the corresponding region (the functions must have steep slopes).

(b) Each symptom function must change above the same region (the thresholds must cluster).

These are precisely the conditions under which a dimensional illness will yield bimodality, and it is argued in the next section that psychiatric research on this issue has systematic biases which tend to ensure that these conditions are met when an illness is dimensional.

Influence of bias on dimensional illness

Types of bias

Most researchers are aware of 'observer bias', outlined by Kendell (1968). Given a particular inventory, a researcher predisposed to a categorical view of the illness simultaneously classifies patients and completes the diagnostic inventory in accordance with his or her predisposition.

Symptom selection bias

The same prejudgement can operate, however, in the initial selection of the symptoms to be included in the inventory, even were it to be subsequently administered by an incorruptible computer. If an illness truly is dimensional and a researcher is predisposed to the (erroneous) categorical view, the researcher's belief or intuition must be based on observation of some sort, and presumably those extreme on the dimension will share characteristics that vaguely define the researcher's mistaken concept of a sick group. Consequently, it is to be expected that the symptoms chosen will be none other than the characteristics discriminating the dimensionally extreme from the rest. That is, the symptoms likely to be included in the inventory will be a biased selection from the possible universe of symptoms, and will have thresholds constrained to cluster about the region on the dimension corresponding to the researcher's mistaken perception of the categories' boundary.

Such a bias, if operative, is compounded by the common advice to exclude items whose overall endorsement probabilities are far from 50% (outside the 20–80% range), at least in study populations constrained to have near-equal representation of the putative sick and well groups.

Subject selection bias

In most applications of the bimodality approach, if not most psychiatric research, the study population is not the community population. Even when the community population is distributed normally along an illness dimension, if study populations overemphasise one or both extremes of this continuum, then they must artificially conform to a disease entity situation. For example, Cloninger *et al* (1985) selected hospitalised schizophrenics to compare with others, and search for bimodality. If, in reality, the illness is dimensional, then such a selected population will not include moderate schizophrenics who fail to appear at hospital, thus creating genuine distinct groups in the artificial study population.

Figure 3 represents the action of these biases. Three symptoms with slopes of 2.0 are shown in part (a). They have thresholds of 0.7, 1.0 and 1.3, indicating the operation of symptom selection bias. The population is the community population. Part (b) shows the effect of overemphasising the extreme 15% of the community population so that they

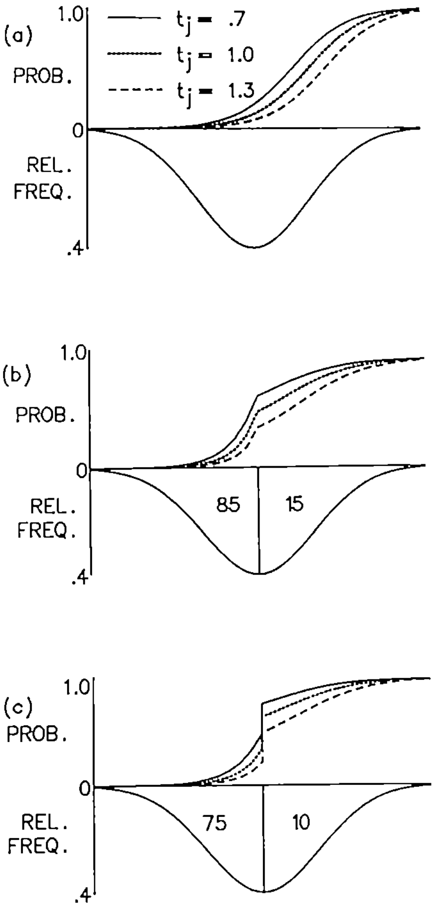

FIG. 3 Influence of biases on a dimensional illness.

become 50% in the study population. Part (c) describes the situation where the lower 75% and the upper 10% are chosen to form the artificial study population. These biases serve to ensure that the conditions required for categorical and dimensional illnesses to manifest identically are in fact met; that is, guarantee that the clustering of thresholds and steepening of slopes required for dimensional bimodality will arise.

Illnesses with two subtypes

The same problems arise in the search for binary disease entities, such as reactive and endogenous depression, although the interplay is more subtle. The study population is usually taken from treated series in hospital or clinics; for example, from hospitalised depressives, in the search for reactive and endogenous categories. As Eysenck (1970) says:

> It seems likely that selection for hospitalization is more in terms of severity . . . than in terms of endogenous or reactive . . . This might easily lead to a predominance of patients combining symptoms of endogenous and reactive depression in hospital, thus . . . disguising any bimodality that might actually exist. Conversely, it is possible that the Newcastle workers have selected patients for inclusion on the basis of extreme scores on Kendell's continuum, thus affecting the shape of the distribution in the opposite direction.

The appearance of bimodality is also related to the selection of symptoms. If the symptoms chosen are those that discriminate endogenous depressives (be they from a category or a dimensional extreme) from normals, and reactive depressives from normals, then they will not discriminate ideally between the two depressions. For this latter task, symptoms are required which are simultaneously endogenous and not reactive (or vice versa). On the other hand, symptoms which discriminate between the two groups may do so on bases other than endogenous versus reactive depression. Two groups of people will differ not only on the criterion used to segregate them, but on a variety of correlated criteria. Such other criteria, each separately correlated with the segregation criterion, need not intercorrelate among themselves, and thus will not produce bimodality, as the following example demonstrates.

Consider a two-symptom inventory applied to two groups of 16 subjects each, classified as endogenous and reactive depressives. Suppose the response patterns (1, 1), (1, 0), (0, 1) and (0, 0) occur with frequencies 8, 4, 4, 0 respectively among the reactives, and with frequencies 0, 4, 4, 8 among the endogenous depressives. For either symptom, the association with the depressive categories is given by the 2×2 table

	Symptom response		
	Yes	*No*	
Reactive	12	4	16
Endogenous	4	12	16
	16	16	32

As discriminators of the classification all items perform well; the χ^2 is 8 on 1 degree of freedom. Yet the number-endorsed distribution is unimodal, even with only two symptoms. Scores of 0, 1, 2 occur with frequencies of 8, 16, 8.

The key to understanding this apparent anomaly lies in the observation that the symptoms are uncorrelated:

		Symptom 1		
		Yes	*No*	
Symptom 2	*Yes*	8	8	16
	No	8	8	16
		16	16	32

Bimodality arises with a preponderance of patterns of two types, almost all zeros and almost all ones. This requires intercorrelations among the symptoms; it is not sufficient that they discriminate well individually. The lack of such intercorrelations indicates that the symptoms are discriminating on unrelated criteria. Constructing an inventory which is heterogeneous in this sense will ensure, even when the symptoms individually discriminate a common classification, unimodality on some dimension which is a pot-pourri of them all. Conversely, an inventory with symptoms tapping the same construct, and with all symptoms centrally located, must yield bimodality whether the construct is dimensional or categorical.

This phenomenon may underlie the apparent conflict between the depression bimodality found by Carney *et al* (1965) and the failure of Kendell & Gourlay (1970*a*) to replicate it. Close reading of the symptom selection procedures of the former shows that a major factor in selection was *a priori* content validity of the symptoms in their instrument, while the latter authors report including symptoms which discriminated their classification but appeared unrelated conceptually to the distinctions between the depressives. They also report excluding symptoms from their final inventory that would usually be included on the basis of their content. Similar comments apply to unimodality found by Kendell & Gourlay (1970*b*) in their search for schizophrenic and affective categories.

Implications

Latent Trait models have been used as a heuristic device to demonstrate that bimodality may arise from a dimensional illness. This counter-intuitive result has not been noticed in the past (Moran, 1966; Maxwell, 1971; Kendell, 1975; Garside & Roth, 1978). Far from being a pathological outcome, the likelihood of such dimensional bimodality is enhanced by symptom and subject selection biases.

Statistical analysis of symptom inventory data

If one accepts the reasoning in this paper then mixture analysis, as recommended by Fleiss (1972) and Everitt (1981), and practised by Cloninger *et al* (1985) is, unfortunately, useless for distinguishing between categorical and dimensional illness models. This statement is no less true of discriminant analysis, factor analysis, clustering, numerical taxonomy (Pilowsky *et al*, 1969) and Boolean factor analysis (Weber & Scharfetter, 1984). All of these techniques are applied to the basic symptom inventory data, and insofar as these data are incapable of distinguishing the two illness models, any subsequent analysis of such data is also incapable of making such a distinction.

The technique of Kendell & Brockington (1980) is also suspect. Non-linearity between an outcome score and a symptom inventory scale score would be quite possible whenever bimodality arises in the latter. Since this can occur with dimensional illnesses, so can the non-linearity they would interpret as a hallmark of categorical illness states.

Recommendations

From this perspective, certain conditions must be met before bimodality can be used to infer that an illness is categorical. First, the study population must not be artificially constructed so that it conforms to a categorical structure if in fact the illness is dimensional. In this sense, the community population is an ideal study population.

Secondly, it must be shown that the symptoms chosen are not preselected on *a priori* grounds which relate to an erroneous belief that the illness is categorical. This is tantamount to ensuring that no symptoms can be found which discriminate among the study population at locations other than the putative boundary between the categories.

Thirdly, the symptoms must be homogeneous, or discriminating among those with and without the disease on the same basis, namely that related to the disease in question.

Even then the inference is more an evaluative judgement than a rejection of the dimensional view on qualitative grounds.

Conclusion

In exploring the ramifications of a dimensional view of illness, the nature of a symptom inventory as an instrument has been emphasised. What is seen of the world is an interactive function of three components: reality, the viewing instrument and the viewer. It is quite possible for reality to be continuous, for the instrument to function best at just one point on that continuum, and for the viewer to point the instrument selectively at that region and to conclude that this region is a qualitative boundary. This is not to say that it is not a boundary, but it is not to say that it is. Before one so concludes, there is an onus to demonstrate that the instrument is not selective, but is perceiving reality as it is.

Where the instrument is a psychiatric inventory, Latent Trait techniques seem the most promising way of unravelling this interaction.

Life Events and Psychiatric Disorder: The Role of a Natural Disaster

ALEXANDER C. McFARLANE

Examining the impact of natural disasters on psychological health provides an opportunity to study the role played by extreme adversity in the onset of psychiatric disorder. Four hundred and sixty-nine fire-fighters who had been intensely exposed to an Australian bushfire disaster completed a detailed inventory of their experiences four months later. They also completed a brief life events schedule and the 12-item General Health Questionnaire. Only 9% of the GHQ score variance could be accounted for by the disaster and other life events; the effects of the disaster appeared to be separate and additive. This is similar to the relationship between life events and psychiatric illness found in other settings. It is suggested that vulnerability is a more important factor in breakdown than the degree of stress experienced.

Much research has tested the hypothesis that adverse life events are causally related to the onset of psychiatric disorder (Brown *et al*, 1976; Paykel, 1978; Tennant, 1983; Cooke & Hole, 1983). Most of this research has examined the additive effect of a range of diverse experiences on psychiatric impairment. An alternative method is to study a population comprised of people who have all experienced the same life event, but with a range of intensities. This research design has been used infrequently. One setting where it might be utilised is in investigating the effects of a natural disaster on psychological disorder, since the individual experiences of disaster victims vary, although they have all been exposed to the same highly distressing event.

Previous disaster research has not universally supported the conclusion of life events research that adversity is causally related to the onset of psychiatric disorder (Green, 1982). There is a range of opinion about the psychological consequences of disasters, extending from the claim that the level of morbidity is high and long-lasting (Gleser *et al*, 1981; Leopold & Dillon, 1963) to the view that disasters have little or no important effect on mental health (Quarantelli & Dynes, 1977). A major reason for this controversy lies in the failure of much disaster research to use a quantitative rather than a qualitative methodology. Green (1982) has argued that future disaster research must carefully document the intensity of exposure and the nature of the losses sustained in the disaster, and must relate these to the levels of psychiatric morbidity.

Many potential problems exist in using this approach, because accepted measures of the impact of a disaster have not been developed. Furthermore, their validation presents problems for most researchers, because major disasters are infrequent. The experience of researchers into other life events could assist in this process of validation.

Although there are a number of common methodological and theoretical issues, there has been little cross-fertilisation of ideas between disaster research and life events research (McFarlane, 1985). For example, it has been concluded that although a link exists between adversity and neurotic impairment, the relationship accounts for only about 10% of the variance of disorder (Tennant, 1983). On the other hand, life events researches generally accept that "disasters show that when psychological stress is sufficiently severe, virtually everyone decompensates and becomes demoralised, dependent, and identifiable as a psychiatric case" (Andrews & Tennant, 1978). Such assertions about the level of psychiatric morbidity following a natural disaster were quantitatively investigated in the present study.

The nature of the interaction between different major adverse life events and the onset of psychiatric disorder is another issue to be examined in disaster victims. Holmes & Rahe (1967) suggested that events had an additive effect, whereas Brown & Harris (1978) assumed that once a single event of sufficient intensity had been experienced, other events were relatively unimportant. If the first hypothesis were correct, the experience of substantial adversity prior to a disaster would have an effect additive to that of the disaster; if the second were correct, prior adversity would have a more powerful association with psychiatric morbidity than would the disaster event.

The present study examined the two hypotheses by investigating the impact of a bushfire disaster on a group of fire-fighters who had varying exposure to it. The first hypothesis was that a significant relationship would exist between the degree of adversity experienced by individual fire-fighters and their level of psychiatric morbidity but that this would not account for more than 10% of the total variance. The second hypothesis was that major adverse life events would show a relationship with psychiatric disorder which was independent of the effects of the natural disaster.

Method

The setting: disaster and fire-fighters

On 16 February 1983 several disastrous bushfires burnt 2804 km^2 of bush, grazing land, orchards, forests, and national parks in South Australia. Twenty-eight people were killed and many hundreds injured, and over 250 000 stock animals were killed. The fire destroyed or severely damaged 385 homes, and 3200 properties were affected in some way. A conservative estimate of the cost of the damage was $A200 million. The psychological impact of the disaster has been reported elsewhere (McFarlane, 1984; McFarlane & Raphael, 1984).

A large organisation of volunteer fire-fighters exists in Australia to combat such fires. Several thousand of these firefighters, living both within and outside the fire-devastated area, attempted to control the blaze. Three were killed, a number lost their homes, others had their stock and farms destroyed, and many were injured. This group provided an ideal opportunity to study the onset of psychiatric morbidity following a disaster, because of its wide range of exposure and losses.

Questionnaire design

A preliminary questionnaire was designed, comprising an inventory of the impact of the disaster, a brief life events inventory, and the 12-item General Health Questionnaire (Goldberg, 1972). It was administered to 26 senior fire-fighters and then discussed with them. Ambiguities were corrected, and several questions added to ensure that a complete description of the fire-fighters' experiences was obtained. The inventory of the impact of the disaster consisted of 15 questions about personal and property losses, 9 about the nature and duration of the fire-fighters' exposure to the fire, and 8 documenting the injuries sustained and the type of treatment received. These allowed an overall rating of severity.

The brief inventory of life events experienced before the fire was based on items 2, 12, 13, 14, 15, 45, and 60 from Tennant & Andrews' (1976) life event inventory. These items focused on financial and legal difficulties, bereavement, and ill-health – factors that might be expected to influence the experience of a disaster. The final part was the 12-item General Health Questionnaire (Goldberg, 1972). This has been validated as a reliable measure of psychiatric impairment in an Australian population (Tennant, 1977), in which setting, used as a 'caseness' measure, it has been shown to have a specificity of 91.7%, a sensitivity of 86.6%, and a misclassification rate of 10%. For correlational analysis the Likert score of the GHQ was calculated. A cut-off of 1/2 was used for definition of 'caseness'; the prevalence of cases was also calculated at a cut-off of 2/3.

Sampling method

The sample was chosen from the volunteer fire-fighting service. This did not have an accessible current membership list at the time of the disaster, and therefore the questionnaires had to be distributed through headquarters staff. They passed them on to the brigade commanders, who in turn gave them to the volunteers. A total of 1500 questionnaires were delivered for distribution three months after the disaster. Despite a request, no record was made of exactly how many of the 1500 questionnaires were given to fire-fighters. No follow-up reminders could be sent to improve the return rate, because the names of the fire-fighters who had received the questionnaires were not recorded. A total of 489 questionnaires were returned, by prepaid postage, a mean of one month later, i.e. four months after the disaster. Twenty questionnaires were excluded because the reponses were not sufficiently complete.

The apparent low return rate of 30% raises the possibility that a potential bias existed in the sampling. However, it may have been an artefact, as subsequent discussion with headquarters staff revealed that a significant number of questionnaires had possibly not been distributed by the brigade officers, some of whom had sustained major losses themselves in the disaster and had no time to spare from reconstruction. A comparison sample of fire-fighters was therefore studied in an attempt to ascertain whether a range of demographic variables, or the nature of the individual's experience of the disaster, had biased the initial sampling. Eleven months after the fire the fire-fighting organisation had updated its membership records and these were made available. Seven brigades, selected on advice from headquarters staff because they were seen to be representative of the fire-fighters in terms of experience of the disaster and membership composition, were chosen for study as a comparison group. The original sample was resurveyed at the same time (this data is not reported in this paper, except for the GHQ scores).

Two follow-up letters were then sent to those comparison group subjects who did not return the questionnaire, to ensure an adequate response rate. By comparing this group with the original sample over a range of variables it was possible to establish the representativeness of the original sample within the organisation. Most members of the fire-fighting organisation were involved in the disaster, so no non-exposed control group was available.

Method of scaling

The range of exposure and losses sustained in the diaster was known to be substantial. The questionnaire was therefore designed to allow separate scaling of four aspects of the fire-fighters' experience of the disaster. Firstly, the personal loss sub-scale recorded the number of people known to the fire-fighter who were killed in the fire and the nature of their relationship to the subject. The weighting of losses was based on the relative weighting for change of the items in the Tennant & Andrews (1976) life events inventory, which has been validated in an Australian population (e.g. death of a close friend = 1, death of a sibling = 2, death of a spouse = 3). The names of all those killed or seriously injured in the fire were published in the media. This made it possible to validate the reporting of deaths or injury in next of kin or first degree relatives by cross-referencing the surnames of the victims with the research subjects. No misreports of personal losses were found.

Secondly, the injury sub-scale was weighted on the basis of the type of treatment required, rather than on reported severity of injury which might have been subjective (e.g. hospitalisation = 3, medical out-patient care = 2, nurse or ambulance officer = 1).

Thirdly, the exposure sub-scale items (which measured the time spent fighting the fire, the use of emergency procedures to protect the fire unit, whether the subject was trapped by the blaze, etc.) were additive and unweighted. The inter-relater reliability of this sub-scale was found to be acceptable by comparing the reports of members of the same units who had had similar, but not identical, experiences of a fire ($r = 0.76$).

Finally, the scoring of the property loss sub-scale covered a range of damage and losses. This included complete destruction of a fire-fighter's home or other property and buildings, as well as damage in varying degrees. Because a number of fire-fighters were farmers, loss of income was also recorded. The items of this sub-scale were weighted according to the amounts of practical assistance require to reparate for losses. The weighting was obtained by surveying the special team of 20 bushfire relief workers appointed to assist the disaster victims, who were able to assess independently the impact of losses in the context of the disaster; their averaged responses were used as weighting. Thus the scaling of losses was not contaminated by the distress generated. The procedure is to be described in more detail elsewhere.

Statistical analysis

The data were analysed using the Statistical Package for the Social Sciences (SPSS) (Nie *et al*, 1975; Hull & Nie, 1981); a probability level of one in twenty was used. Groups were compared using chi-squared, Mann-Whitney *U* and Student's *t*-tests, according to the characteristics of the variable being examined. The variance of the GHQ score was investigated using a multiple regression analysis (Hull & Nie, 1981) which only examines the contribution of significantly loading variables. Pearson's correlation coefficients were calculated, because of the size of the sample studied and because the SPSS only computes regression analyses using parametric statistics.

Results

Sample

When the original cohort of 469 fire-fighters was compared with the comparison group on a range of demographic variables, several statistically significant, but small, differences emerged (Table I). The mean age of the study sample was less by two years than that of the comparison group, and the comparison group was of slightly higher social class (Krupinski *et al*, 1966), more of its members being farmers. The two groups' experience of the disaster, measured by the sum of their fire-related experiences, was not significantly different, and they did not differ significantly on GHQ scores.

Disaster experience

Individual experience of the disaster varied widely. Some degree of property damage was suffered by 23% of the sample, in many cases enough to affect their livelihood. None of the subjects had lost a first degree relative,

[1] Based on questionnaire score.

although 7% had experienced some bereavement due to the death of a more distant relative or close friend. The mean during of time fighting the fire was 15.6 hours. During that time 19.7% of subjects believed they had come close to dying, and 41.2% had had to protect themselves from the fire using emergency procedures. Of the 26.6% injured, 12% had been admitted to hospital.

Relationship between GHQ and fire experience

The relationship between the GHQ and a range of variables was examined (Table II). Most fire-related variables were significantly correlated with the GHQ score, with the exception of personal loss and injury. Experience of previous fires was also significantly associated with the GHQ score, although age and social class (Krupinski *et al*, 1966) were not. Experience of recent adverse events prior to the disaster was significantly correlated correlated with the GHQ score. The size of these correlation coefficients was generally small, in part owing their significance to the size of the sample.

TABLE III
Comparison of cases with non-cases (as defined by GHQ scores)

[1] Based on GHQ$\geq$2.

The 146 'cases', defined by using a cut-off point of 1/2 on the 12-item GHQ, were compared with 311 'non-cases' (Table III). On all variables that were significantly different, those subjects demonstrating psychiatric impairment had a higher level of exposure to the disaster. Again, personal loss and injury were not significantly different between cases and non-cases.

Prevalence of disorder

The prevalence of cases among the fire-fighters was 30% using a 1/2 cut-off. When the 2/3 threshold was used, the prevalence was 23.2%.

Variance attributable to the disaster

The proportion of the variance of psychiatric impairment that could be explained by experience of the disaster and other recent life events was examined using stepwise multiple regression analysis of the GHQ. The fire-fighters' exposure, perceived threat, severity of injury, personal loss, property loss, and the recent events score were included in the equation. The only significantly loading variables were property loss, accounting for 4.9% of the variance (multiple $r = 0.23$, adjusted $r^2 = 0.049$, $f = 19.03$, $P = 0.000$), and recent life events, which predicted a further 3.8% (multiple $r = 0.30$, adjusted $r^2 = 0.087$, $f = 17.69$, $P = 0.000$). None of the other variables predicted a significant percentage of the variance.

Discussion

The data from this study provided support for the first hypothesis, i.e. that a significant relationship would exist between the degree of adversity experienced by individuals in a disaster and their level of psychiatric morbidity. However, it should be noted that this relationship was weak. For example, although the cases and non-cases were significantly different on a number of fire-related variables, the differences in mean values were not great.

The second hypothesis, about the magnitude of this association, was supported by the finding that only 9% of the variance of the GHQ could be accounted for by the disaster and recent life events. This confirms the strength of the association previously postulated as existing between life events and the onset of psychiatric disorder (Andrews & Tennant, 1978; Paykel, 1978). Thus a consensus arises from two quite different methodological approaches – one looking at the effect of multiple random life events (Holmes & Rahe, 1967; Tennant & Andrews, 1976; Paykel *et al*, 1971) and the other, employed in this study, looking at the impact of one threatening and destructive event.

There was also support for the last hypothesis examined: that major adverse life events have independent relationships with psychiatric disorder. Firstly, the effect of the disaster was independently associated with psychiatric impairment, not being 'partialled out' in the regression analysis by the contribution of threatening life events experienced before the fire. In other words, people who had experienced life events before the fire remained equally, if not more, susceptible than others to the emotional effects of the disaster itself.

Secondly, the impact of the disaster was sequential in time, the fire-fighters being exposed to the disaster before being in a position to establish their personal and property losses. All but 9% were unable to defend their own property, because they were fighting the fire elsewhere. Although exposure and perceived threat correlated with the GHQ score, the most powerful association was with property loss (Table II). It is probable that the ongoing stresses of property loss, such as loss of income for farmers, accounted for the strength of the association, which provides further support for an additive effect. Furthermore, the fact that the two variances (i.e. that accounted for by events experienced prior to the disaster and that accounted for by the disaster itself) were of a similar order of magnitude supports the view of Holmes & Rahe (1967) that major adverse life events have an additive and relatively independent effect.

This study demonstrates that investigating the psychological impact of a natural disaster provides an opportunity to examine the relationship between minor psychiatric disorder and a recent life event in the absence of several methodological problems often encountered in life event research (Paykel, 1983). This is because recall of a disaster is likely to be more consistent than that of other events, its impact is easier to document than that of a wide range of life events (Finlay-Jones, 1981), and a disaster is not a consequence of illness (Brown, 1974).

However, the current study has limitations that need to be considered in the interpretation of the data. Firstly, the questionnaire return rate was low, as is often the case in disaster research (Logue *et al*, 1981). However, the study sample was not skewed to any substantial degree. In particular, the fire-fighters studied and the comparison group did not significantly differ in their experience of the disaster or the prevalence of psychiatric morbidity, the two variables that would have suggested biased sampling. Secondly, the inventory used in this study has not been formally validated. However, there appeared to be face validity in its construction. For example, in the personal loss sub-scale the weighting was based on a carefully validated life events scale measuring these same losses (Tennant & Andrews, 1976). Formal validation can only occur following a disaster, and such events are infrequent. To this end, Green (1982) has called for careful reporting of quantitative methodology so that standardised check-lists can be developed for disaster research. The present paper is an attempt to begin the process.

Finally, it is difficult to know how typical this population was of the victims of the Ash Wednesday disaster. While it is reasonable to speculate that fire-fighters were significantly affected by exposure to the disaster, the study does not establish whether the same magnitude of association between experience of the fire and psychiatric impairment would occur in an unbiased community sample.

However, fire-fighters are of particular interest because, unlike others involved in disasters who, in general, attempt to protect themselves, most of these people were committed to facing extreme danger for hours on end, as well as risking serious injury and substantial personal and property losses. This would suggest that the relatively small association between psychiatric impairment and exposure to the disaster cannot be explained away by a relative absence of danger or loss.

Furthermore, the validity of these data is substantial because a number of potentially confounding variables, often present in disaster victims, were not operating. Two factors that can influence the reporting and prevalence of neurotic impairment among disaster and accident victims are compensation payments for psychological trauma and the neurological sequelae of head injuries (Lishman, 1973). The voluntary nature of the organisation to which the fire-fighters belonged, and the absence of head injuries among them, meant that neither of these potentially confounding variables was operating here.

In conclusion, the data suggest that the majority of the fire-fighters studied did not become cases, despite experiencing prolonged life-threatening stress, frequent injury, and property loss. This raises the possibility that psychiatric morbidity in a population affected by disaster can perhaps better be explained using a model where the disaster acts as a trigger to most of the individuals who are already vulnerable to decompensation (Hendin *et al*, 1983; McFarlane, 1984). If this proposition is correct, the exact prevalence of cases following a disaster may be more influenced by the prevalence of premorbid risk factors than by the severity of the disaster. Although the prevalence of psychiatric impairment in a population after a disaster may be substantial, such a trigger effect would lessen the size of any linear correlation between the disaster experience and psychiatric disorder if individual thresholds for decompensation were variable, as has been suggested by Paykel (1978). This may explain why only 4.9% of the variance of minor psychiatric disorder in this population could be explained by the intensity of the individual's disaster experience.

The small proportion of the variance of disorder successfully accounted for in this population raises the question of what factors may explain the rest of it. Some disaster literature has proposed that problems with mental health, where they exist, can be attributed to the destruction of kinship or social networks (Perry & Lindell, 1978). However, these firefighters had high levels of social support before, during, and after the disaster from within the firefighting organisation. Also, two studies of psychiatric morbidity among victims of this same bushfire disaster found little or no relationship between social support and the GHQ score (Hill, 1983; Wallace *et al*, 1985). Thus lack of social support did not appear to be a major factor contributing to psychological impairment.

Therefore, the other variables which may influence an individual's vulnerability to psychiatric morbidity following a disaster – such as genetic predisposition to psychiatric disorder, personality type, psychodynamic characteristics, and family relationships – all require further investigation. If preventive mental health services are to be provided after disasters, definition of the characteristics of those who are at risk of decomposition is of central importance.

Acknowledgements

Drs R. Goldney and D. Ben-Tovim are thanked for advice about the preparation of the manuscript, Ms V. Blumbergs for statistical assistance, Ms J. Tamkin for typing the manuscript, and Mr L. Johns and his staff for their assistance in distributing the questionnaires. This research was supported by the Flinders Medical Centre Research Foundation.

The Maternity Blues in Post-partum and Post-operative Women

V. LEVY

In order to establish whether the maternity blues is peculiar to the puerperium a self-rating blues questionnaire was administered to women after childbirth and after surgery. A period of dysphoria, similar in many respects to the maternity blues, was experienced by women post-operatively. The main difference between maternity and post-operative patterns of dysphoria seemed to lie in the timing of the blues, but on closer analysis many post-operative dysphoric symptoms peaked in a similar way to those in the maternity group. In the search for the cause of the maternity blues it may be helpful to study the same parameters in post-operative dysphoria.

The maternity blues is a poorly defined but common condition occurring in 50–70% of women in the early puerperium (Yalom *et al*, 1968; Pitt, 1973). The condition is characterised by transient periods of dysphoria, manifested by crying, feelings of depression and despondency, confusion, anxiety and insomnia (Robin, 1962; Kane *et al*, 1968, Yalom *et al*, 1968; Pitt, 1973; Priest, 1979). Detailed descriptions of the condition have been provided by Yalom (1968) and Stein (1982). The cause of this dysphoria is unknown, but it has been suggested that the rapid fall in sex hormones could be responsible. A fall of this magnitude is unique to the early puerperium. One way of testing whether or not the blues is caused by a fall in hormone levels would be to determine whether the blues syndrome is unique to the early puerperium. It is known that some dysphoria occurs after surgical operations. Raphael (1974) found that 60% of women experienced a bout of crying, sadness and uncontrolled distress 4–5 days after hysterectomy. However, more systematic information has not been reported regarding the frequency and nature of post-operative dysphoria.

The purpose of this study is therefore to determine whether a maternity blues-like syndrome occurs in post-operative women and, if so, to see if there is any characteristic pattern which distinguishes post-partum from post-operative dysphoria.

This preliminary study investigates and compares the manifestations and incidence of the blues between three groups of women: following childbirth, following major surgery and following minor surgery.

Method

Patients in the study comprised 37 puerperal women, 28 women after major surgery and 22 women after minor surgery. All were under the age of 50. Those delivered of a stillbirth or whose baby was seriously ill were excluded from the study, as were terminally ill post-operative patients. Apart from these exclusions, all women delivering or undergoing surgery over a short period of time were invited to take part in the study.

In the post-partum patients, 30 had been delivered normally and seven by forceps. No general anaesthetics were given. The mean age was 26.5 years (range 16–40).

The major operations were defined, arbitrarily, as surgery necessitating a stay in hospital for at least 48 h after operation and included hysterectomy, (two of the 11 hysterectomy patients also had bilateral oophorectomies), lumbar disectomy, lumbar sacral fusion and appendicectomy.

Minor surgery (necessitating a stay in hospital for less than 48 h after surgery), included dilatation and curettage, laparoscopy, meniscectomy, and arthroscopy. Terminations of pregnancy were not included. The mean age of the female post-operative patients was 37.7 years (range 17–50).

A blues-rating questionnaire (Stein, 1980) was completed by every respondent from days 2 to 6 inclusive, following delivery or operation. The questionnaire is a 13-category self-rating scoring system. Insomnia was added as an extra category. Patients discharged before the end of the observation week were asked to complete the questionnaire at home.

The distribution of scores was compared between the post-partum and surgical groups, using the χ^2 test of association. The numbers of patients experiencing each symptom were also calculated (as a percentage of the total number of patients in the group), on a daily basis in order to compare patterns of dysphoria between the groups throughout the week.

In-patients experiencing the blues were asked if they could identify the cause of their distress, how they were helped, whether or not they felt they could have been helped more, and by whom.

Results

A total of 110 women were asked to participate in the study; 87 completed sets of forms were returned giving a response

TABLE I
Comparison of score distributions between post-partum and post-operative groups

Symptom	*Major surgery*	*Minor surgery*	*d.f.*

− Symptom less severe than in post-partum group.

rate of 80%. Non-respondents comprised 30% of the post-partum group, 5% of the major surgery group and 30% of the minor surgery group. A possible reason for the higher response rate in women having major surgery is that most were in-patients for the study week, facilitating return of their questionnaires.

Patterns of symptoms throughout the week

In the post-partum group the number of patients experiencing symptoms peaked on days 3 and 4, whereas the numbers in the surgical groups declined progressively throughout the week and did not show a peak (Fig. 1).

On examining the numbers of patients experiencing individual symptoms, however, it may be seen that many of the individual symptoms in the major surgical group peaked in a similar fashion to those of the post-partum group. The peaking phenomena were not so evident in the female minor surgery groups (Fig. 2).

Summary of comments made by women experiencing the blues

The woman could rarely give convincing reasons for crying; many were puzzled by their tears as crying for them was an unusual reaction. Some blamed their distress on somatic causes such as pain with perineal stitches or post-operative pain. Problems with the baby upset many post-partum patients and may have triggered the blues. Some women cried because of pleasant events; their tears came easily for a variety of reasons, not just because of unpleasant depressing experiences. Many women described a feeling of tearfulness building up through the day which culminated in an uncontrolled bout of crying at the arrival of visitors or some other event, such as news that the baby would have to undergo phototherapy because of neonatal jaundice.

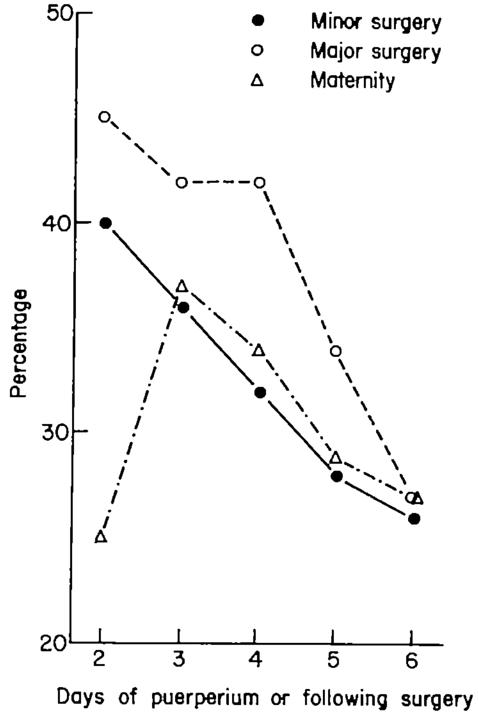

FIG. 1 Percentages of patients experiencing symptoms.

During her distress, every woman who experienced the blues wanted only her husband (or other close relative) with her, or else wanted to be left alone. Some said they felt foolish, as they could give no reason for their tears, and because of this preferred to shut themselves away to cry in private. No-one felt that the nurses or midwives could help, although in several cases they had tried.

Violent dreams featured in a few women's distress. These dreams involved danger and injury to themselves and their families.

Women in the post-partum and major surgical groups made very similar comments regarding their distress. No comment was peculiar to one group. No attempt was made to elicit comments from women discharged home before the onset of their distress, but a few nevertheless supplied comments that reflected those made by the women in the other groups.

Discussion

The present study has demonstrated that the dysphoria called the maternity blues is not unique to the puerperium. A similar type of dysphoria appears to occur in women following surgery; indeed there was slightly more dysphoria in the major surgical group than after childbirth. The only important difference between post-operative dysphoria and post-partum dysphoria appears to be in

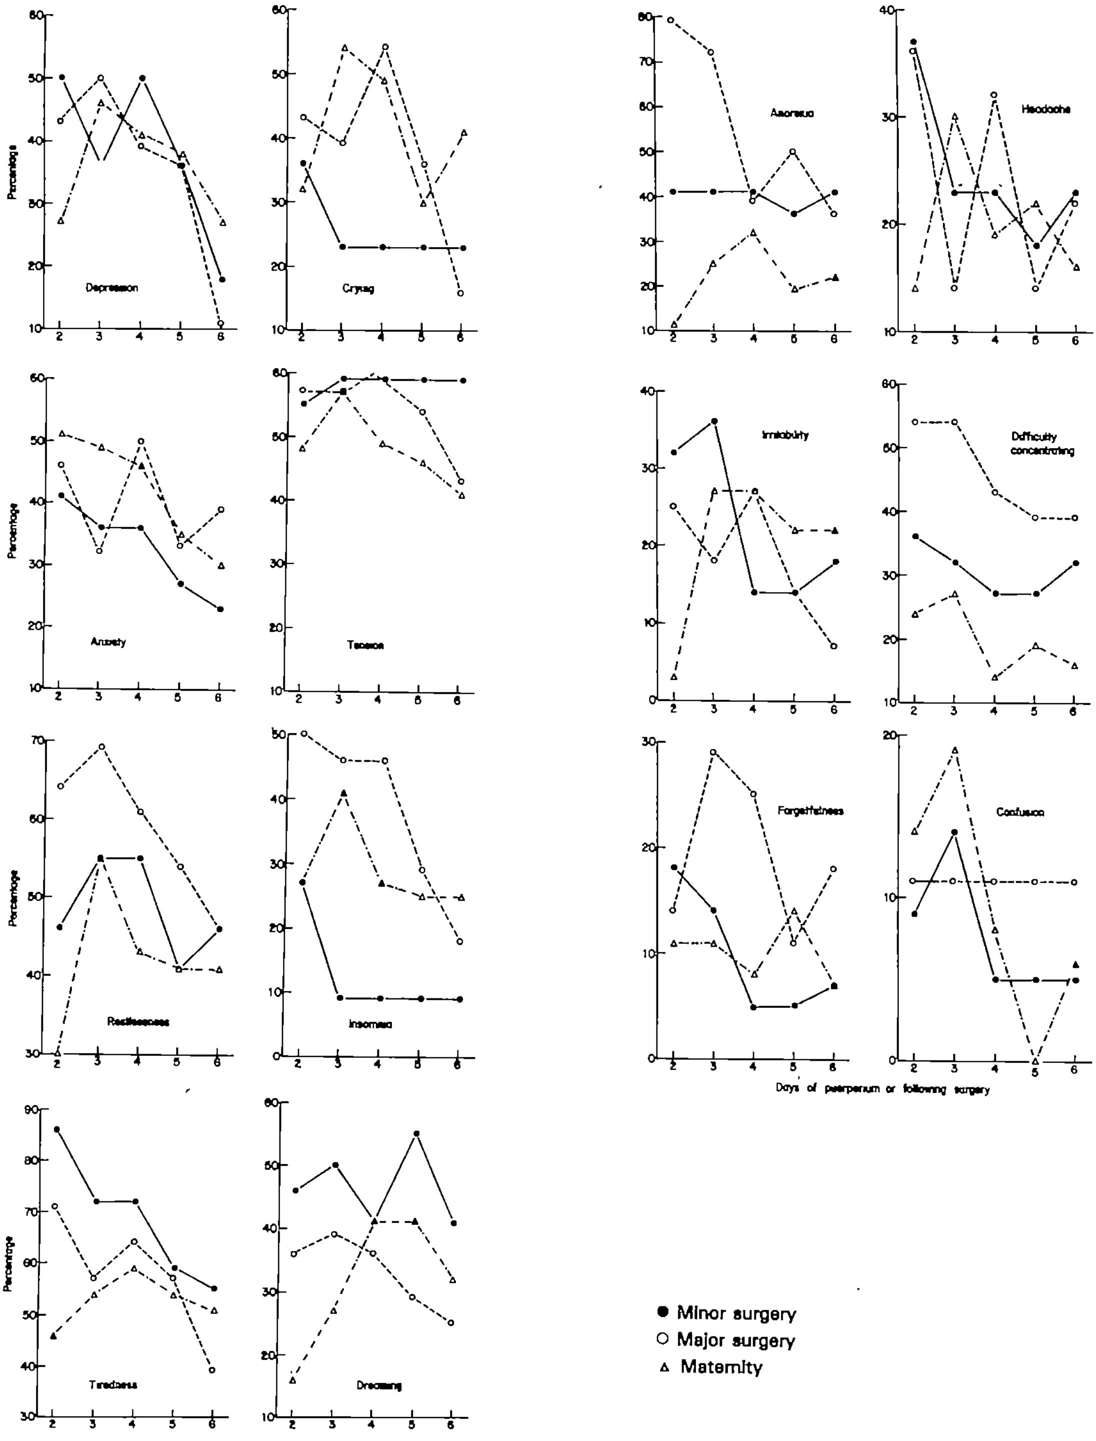

FIG. 2 Percentages of patients experiencing individual symptoms.

the timing. In this study it was found that post-partum dysphoria showed peaking on days 3 and 4, whereas post-operative dysphoria tended to be worse immediately after the operation and progressively diminished. This finding is consistent with those of Pitt (1973), Stein (1980), and more recently Kendell *et al* (1984). Kendell found that mood changes after Caesarean section peaked on day 5 in a similar fashion to those following vaginal delivery, but found no peaking following hysterectomy; instead, hysterectomy mood change ratings fell progressively from day 2 onwards. However, looking at individual symptoms in patients undergoing a wider spectrum of surgical operations, this present study shows that several symptoms (particularly crying and depression in women undergoing major surgery) peak in a similar way to the post-partum group, and indeed, many post-operative patients indicated by their comments that their blues occurred suddenly and unexpectedly at or around post-operative day 4. Differing patterns may perhaps be partially explained by the general physical discomfort experienced in the early post-operative days, particularly following major surgery, or alternatively by ward procedures. For example, surgical insomnia scores start at a high level and then decline through the rest of the week, whereas post-partum insomnia scores peak on day 3. This probably reflects the ward practice of 'rooming in' the mother with her baby from the second or third night onwards, thus making more difficult a good night's sleep for the mother.

In his study of 37 post-partum patients Stein (1980) found the peaking symptoms to be depression, crying, irritability, restlessness, dreaming and headache, whereas exhaustion, poor concentration and anorexia started at a relatively high level and declined throughout the rest of the week. This present study has identified symptom patterns similar in many respects to those described by Stein.

The cause of the blues remains uncertain, despite extensive biochemical investigation. An underlying assumption of these investigations is that the blues is a condition peculiar to the early puerperium, and that biochemical changes occurring after childbirth are therefore likely to be responsible. The present study suggests, however, that the blues is not unique to the puerperium and hence it is unlikely that the large drop in sex hormones is responsible. Cortisol is known to rise in pregnancy and post-operatively and has been implicated in mood changes. If post-operative dysphoria is precipitated by an increased output of cortisol, then it could be expected that major surgery, which causes greater adrenal stress, would result in a higher incidence of dysphoria than minor surgery, and this has been found to be the case.

Endorphins have also been implicated in mood changes (Koob & Bloom, 1983), and have been shown to increase during surgery (Cohen *et al*, 1981), and during pregnancy, and labour (Thomas *et al*, 1982). Newnham *et al* (1984), however, found no correlation between the post-partum blues and endorphin levels.

Whatever the precise cause of the post-partum blues, it is probable that the dysphoria is a reaction to a period of acute stress. Yalom *et al* (1968) mentions the similarity of the post-partum blues to the 'end phenomenon' – a dysphoric reaction noted after periods of intense stress experienced during, for example, paratroop training.

As this is an exploratory study, no attempt was made to control for the type of operation, delivery, length of stay in hospital or medication given, and this has probably affected the results to some extent. Nevertheless, the results of this study strongly suggest that the transient dysphoria commonly seen in the early puerperium and known as the maternity blues is also experienced by women a few days after surgery. In the search for the cause of the maternity blues, it may therefore be helpful to study the same parameters in post-operative dysphoria.

Newly delivered women and their families are often aware of the possibility of the maternity blues, but patients undergoing surgery are not. In view of the puzzlement and concern caused by the blues, it may be helpful to warn women undergoing surgery of the possibility of post-operative dysphoria.

The General Health Questionnaire and the Detection of Emotional Disorder by General Practitioners

A Replicated Study

A. P. BOARDMAN

This paper reports on a study of psychiatric morbidity in 920 patients attending 18 General Practitioners in Lewisham, South East London. Two indices of morbidity were computed on the basis of the patients responses to the General Health Questionnaire (GHQ) and the GPs' own estimates. Indices of the GPs' detection ability were found by comparing questionnaire and GP rating. The results are compared to those obtained by other workers in a sample of Manchester GPs. The GHQ gave a prevalence estimate of 42.9% which is comparable to that of 39.6% obtained in the Manchester study. In addition, the variation in caseness across sociodemographic groups was consistent with the Manchester findings. The GPs' estimates of morbidity, while much lower than those obtained in Manchester, have similar sociodemographic profiles. The results support the use of the GHQ as a screening device in epidemiological studies, and suggest the need for further investigation of the individual GP's performance as a case detector.

Over recent years the focus for epidemiological research in psychiatry has shifted from hospital to community, with resultant problems for definitions of caseness (Williams *et al*, 1980). This advance has produced a wealth of evidence which suggests that the bulk of psychiatric morbidity is seen at the primary care level and that only a small proportion of this is passed on to the psychiatric services. Statistics pertaining to this large group vary considerably depending on the case finding methods used (Hankin & Oktay, 1979). The reported rates of psychiatric illness show a great variation between individual physicians. Shepherd *et al* (1966), for example, showed a nine-fold variation of rates of reporting between GPs in their sample of London GPs, and Marks *et al* (1979) found that an average of 31.1% of patients were identified as 'psychiatric' with a range 3–77%. Importantly, however, less variation in morbidity is seen if screening tests or interview methods are used, suggesting that the variation of reported rates represents a large degree of observer bias. Furthermore, no correlation is found between the level of disorder reported by the GP and the level predicted by the screening questionnaire (Goldberg & Huxley, 1980).

This variation and discrepancy between GP and questionnaire measures has been shown to hold in other countries, for example Australia (Chancellor *et al*, 1977) and the USA (Hesbacher *et al*, 1975; Goldberg *et al*, 1982).

Studies investigating the sources of this inter-practitioner variation in reporting have identified factors in both the patient and the doctor. Shepherd *et al* (1966) explained 33% of the variance in terms of sociodemographic factors, in particular the number of patients joining and leaving the practice lists. Another important source was the doctors' attitudes, in particular those measured on a sub-section of the attitude questionnaire labelled 'psychosomatic score'. This score reflected the GP's assessment of the importance of psychological factors in the aetiology of listed diseases (e.g. asthma, peptic ulcer, cancer). Doctors who thought such factors important tended to report high numbers of psychiatric cases. Marks *et al* (1979) identified a number of patient stereotypes that alert the GP to the possibility of psychiatric illness, notably the separated and widowed and individuals seen by the GP several times previously. They also found the interview style and personality of the practitioners to be factors of importance in detection ability. The Australian study of Chancellor *et al* (1977) identified sociodemographic variables which were congruent with questionnaire measures (separated, widowed and divorced) while women over 45 years of age were over-diagnosed and men in the same age range under-diagnosed. The US study of Goldberg *et al* (1980) was an attempt to replicate Marks *et al* (1979) and found overall similar results with regard to doctor factors, however, there were some specific differences which were thought to be due to the new measures introduced into the US study.

In the detection studies mentioned above (with the exception of Shepherd *et al* (1966)) the criterion against which the GP's performance was judged was the patient's score on the General Health Questionnaire (GHQ) (Goldberg, 1972).

The GHQ was designed as a screening instrument for non-psychotic disorders and has, to date, been used in a wide range of studies. Its validity in general practice populations appears to be well established (Goldberg, 1978). However, the performance of GPs as case detectors relative to the GHQ requires further investigation. The Manchester study of Marks *et al* (1979) identified several patient factors that affected case detection by GPs. It is not known whether the factors generalise to other GPs in different parts of the UK. That is, do patient stereotypes underlying detection represent rigid stereotypes or do they vary among different groups of GPs?

The present study is part of a larger investigation designed to evaluate a community psychiatric clinic, the Mental Health Advice Centre (Bouras & Brough, 1982). One facet of this investigation was to estimate the prevalence of minor psychiatric morbidity and the detection abilities of a selection of GPs who refer patients to the clinic. It is this aspect of the investigation that will be reported in this paper.

The aims of the present report are: to report on the probable prevalence of emotional disorders as measured by the GHQ in general practice; to compare the detection of emotional disorders in two groups of GPs in different parts of the UK; and to assess whether sociodemographic variables associated with case detection represent rigid stereotypes.

Method

The survey took place in Lewisham, South East London. Thirteen General Practices were approached whose surgeries lay within the geographically defined catchment area of the Mental Health Advice Centre (MHAC). Eight practices agreed to take part. No attempt was made to obtain a random sample of GPs. The practices were chosen solely on the basis of their location as the study was designed to provide a description of the practices whose patients were potential referrals to the MHAC.

The design represents a partial replication of the investigation reported by Marks *et al* (1979).

The survey was carried out between October and December 1983. Each practice was surveyed for a period of 1 week. Consecutive patients between the ages of 16 and 65 years who attended the surgeries to see their GPs were asked by the author to complete the 28-item GHQ before seeing the GP. Sociodemographic data was also collected from the patient. Patients who were not attending for 'illness' reasons (e.g. innoculations, insurance examinations, routine ante-natal visits) were not approached. The GP was asked to complete a simple form after seeing the patient on which s/he rated the patient's degree of emotional disturbance on a 6-point scale ranging from 0 - no disturbance to 5 - severe disturbance. This scale was identical to that used by Marks *et al* (1979). Each GP was instructed by the author in the use of the scale. The GPs were not aware of any patient's GHQ scores during the week of the study.

The two ratings obtained from the GHQ and GP scale were used to compute the four main dependent variables which were:

(a) Conspicuous psychiatric morbidity (Kessel, 1960). This refers to the percentage of patients rated by the GP as psychiatrically ill. On the 6-point scale it represents a rating from 2–5 inclusive.
This gave the index of GP caseness.

(b) Probable prevalence of psychiatric illness. This represents the proportion of patients who obtain a high score on the GHQ after a correction term has been applied. The correction term is given by the formula:

$$\text{Probable prevalence} = \frac{HP - fp}{s - fp}$$

Where:
$HP = \%$ with high scores; $fp =$ false positive rate $= 1 -$ specificity; $s =$ sensitivity.
In the case of GHQ-28, a cutting score of 4/5 was used. At this cutting score in general practice settings the questionnaire has a sensitivity of 85.6% and a specificity of 86.8% (Goldberg, 1978).

(c) Spearman's correlation coefficient (ϱ). This was computed by a comparison of the GP's ratings and the GHQ score. This statistic can be used as a measure of the accuracy of the GP's assessment, where accuracy refers to the overall ability of the doctor to make assessments of psychiatric disturbance which are congruent with the patient's symptom levels.

(d) Identification index. This is a measure of the ability to identify symptomatic patients as sick and ignores the ability to identify symptomatic patients as normal. As such it is an assessment of the physicians performance as a case detector it can be found using the formula:

$$\text{Identification Index} = \frac{\text{Number of patients identified as ill by GP and GHQ}}{\text{Number of high scorers (GHQ)} \times \text{sensitivity}}$$

In addition to these, 'bias' was calculated for each GP, this represents the tendency of the physician to make or avoid making psychiatric assessments. It is computed by comparing the conspicuous psychiatric morbidity to the probable prevalence:

$$\text{Bias} = \frac{\text{CPM}}{\text{Probable prevalence}}$$

This was not reported by Marks *et al* (1979) but a figure for their overall sample of GPs is available in Goldberg & Huxley (1980). Since the CPM is generally not correlated with probable prevalence it can be considered to be largely a measure of bias. Thus, in this report, as in Marks *et al* (1979), CPM will generally be used as the measure of bias.

Results

Eight General Practices took part. They consisted of 18 GPs–six female and twelve male – in three single-handed and five group practices.

In the specified age group 983 patients attended the surgeries. Of these 63 were missed by the researcher during the surgery time. Therefore, some information was obtained on 920 patients. Of the 920 patients, 44 did not complete the GHQ. Reasons for not completing the questionnaire were: refusal (21), language difficulties (9), handicapped (11). Three questionnaires were incomplete.

The low rate of refusal confirms the acceptability of the GHQ to patients (Goldberg, 1972).

GP ratings were obtained on 809 of these patients. Some of the patients given the GHQ attended a trainee in one of the practices who did not take part in the ratings. The GHQ ratings obtained on these patients where included in the computation of the overall probable prevalence.

The overall results for the Lewisham doctors are shown in Table I where they are compared to those reported in the Manchester study. It is important to note that the overall probable prevalence of 42.9% is comparable to that of 39.6% reported in Manchester. However, the Lewisham GPs consider only 19.3% of the patients to be cases while the Manchester GPs were more liberal in their estimation (31.1%). The present results confirm the widely noted observation that GPs vary considerably in their detection abilities and provide an unreliable index of morbidity in epidemiological studies. The use of a standardised technique, however, appears to give comparable results.

The most striking differences between the detection abilities of the two samples are the lower bias and identification indices of the Lewisham GPs. The accuracy of both samples is similar. It is likely that the low identification index is a secondary effect of low bias since for a given level of accuracy as bias decreases the number of symptomatic patients correctly identified as cases will correspondingly decrease.

Correlations between the variables are shown in Table II. They are generally higher than those obtained in the Manchester sample. While the most obviously different correlation is that between Rho and CPM, in the Lewisham sample this correlation does not attain statistical significance. If bias is used instead of CPM, the correlation rises to 0.42 but remains non-significant. As with the Manchester study there is no correlation between probable prevalence and CPM. In both groups of doctors there is a moderate correlation between accuracy and identification index and a high correlation between identification index and CPM. In the Lewisham sample if bias is used rather than CPM, this last correlation rises to 0.95.

These correlations then, are similar and the present results confirm the lack of agreement between estimates of morbidity provided by screening questionnaires and by physicians. In addition they suggest that while the Manchester and Lewisham doctors are different in their detection abilities the relationship between the detection indices is similar in both groups.

The remaining results will concentrate on the socio-demographic characteristics of the patients and their effect on the four main variables (summarised in Table IV). At each stage a comparison will be made with the Manchester data.

TABLE I
Overall results

	Mean	*s.d.*	*Range*
Present Study – 19 GPs – 920 attenders			
Conspicuous psychiatric morbidity	19.3%	12.0	0.00–36.6%
Probable prevalence	42.9%	14.00	10.7–62.6%

Sex

The results on this variable are summarised in Fig. 1. As in the Manchester study doctors perceive more illness in female patients (20.4%) than male patients (16.5%). This does not reach statistical significance ($\chi^2=1.52$, $P<0.2$). Although female doctors report fewer cases than male doctors, these differences do not attain statistical significance.

The GHQ confirms the finding of the Manchester study that there is probably more psychiatric illness among female attenders ($\chi^2=4.05$, $P<0.05$). As with the Manchester study this is only true for those women attending male doctors ($\chi^2=5.98$, $P<0.02$). Marks *et al* (1979) explained this finding by the selective recruitment of symptomatic men to female doctors. However, this is not the whole picture in the present study. In the Lewisham practices there is a significantly higher probable prevalence in women consulting female doctors than those consulting male doctors ($\chi^2=4.48$, $P<0.05$). The Manchester study found no significant differences in probable prevalence between female patients consulting male doctors and patients of either sex consulting female doctors. Further to this, it was also found that in the Lewisham practices significantly more symptomatic males consult female doctors ($\chi^2=8.65$, $P<0.01$). Thus, more symptomatic people of both sexes consulted female than male GPs in the present sample ($\chi^2=9.75$, $P<0.01$).

This finding is highlighted by the additional observation that proportionately many more women consult female rather than male GPs (80.5% vs 57.5%) and consequently proportionately less men. Overall, 79% of consulting men see male GPs. This suggests a real recruitment of symptomatic males to female GPs and in this way confirms the Manchester finding.

A possible explanation for this is that symptomatic patients may be avoiding doctors with low bias. Table IV shows the relationship of the GPs bias to high and low prevalence situations. It appears that high prevalence is associated with a low bias which is contrary to that expected. However, all the female GPs have a low bias and high prevalence. When the female GPs are removed from the contingency table the relationship between bias and prevalence disappears ($\chi^2=2.1$, NS). Thus, the relationship between bias and prevalence for the whole sample of doctors is explained by the association of high prevalence and low bias in female GPs. This suggests that the recruitment of symptomatic patients to female GPs is due to the sex of the GP and not the GPs bias.

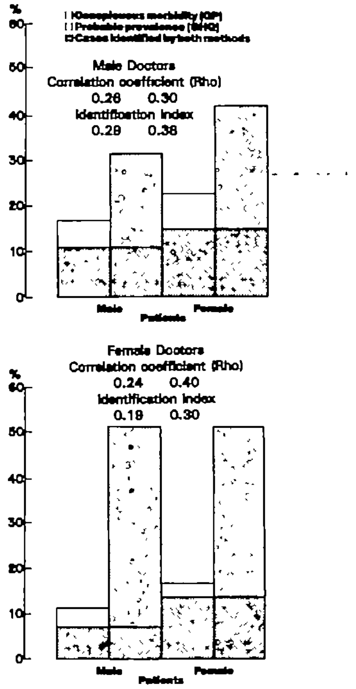

FIG. 1 The effect of sex of the doctor and sex of the patient on the four main variables.

The findings for Rho and identification index only partly confirm those of Marks *et al* (1979). As with the Manchester study identification index is lower for male patients than for female patients irrespective of the sex of the doctor. None of these figures attain statistical significance in the present sample. Contrary to the Manchester sample, overall accuracy is lower for male patients than female patients irrespective of the sex of the doctor. Again these findings do not reach statistical significance.

Age

GP cases show a peak in middle age ($\chi^2=19.43$, $P<0.01$). This is consistent with the probable prevalence, but this also shows a peak in younger age groups ($\chi^2=27.98$, $P<0.001$). This is similar to that found by Marks *et al* (1979). As with the Manchester study identification index reaches its highest values in middle age.

TABLE III
The effect of sociodemographic variables on the four main variables

	Conspicuous morbidity (GP): %	*Probable prevalence (GHQ): %*	*Case identified by both methods: %*	*Identification index: %*
Sex

African	11.8	51.4	5.9	0.13
Indian	7.7	3.3	0.0	0.0
Other	20.0	27.6	16.7	0.49

In both the Manchester and Lewisham samples, the GHQ shows a tendency to identify more cases than the GP in all age groups. This is especially marked in patients between 16–30 years. It is least marked in those patients over the age of 60 years.

Employment status

The rates for psychiatric illness is highest among the unemployed ($\chi^2=24.6$, $P<0.001$). However, this is not reflected in the GP ratings who apportion the highest caseness to housewives ($\chi^2=22.76$, $P<0.001$). Other occupational groups are not significantly different from chance expectancy on either index. In the Manchester sample the unemployed were the largest group on both indices.

Discrete differences are seen with regard to identification index for this sociodemographic group in the Manchester and Lewisham samples. In the present sample, identification index is highest for housewives and lowest for those in

1. $n = 5$

full time employment have similar rank orderings in both samples.

If the data are broken down by sex (Table V) the higher female rates are not accounted for by the idea that housewives are more symptomatic than unemployed women and therefore inflate the female mean. A female patient giving her employment status as unemployed is much more likely to be a GHQ case than one who is a housewife (78.4% vs 44.2). This result is in keeping with Manchester study. The effect of employment status on GHQ caseness appears to be due to the high percentage of unemployed women who were symptomatic.

Marital status

The conspicuous morbidity is highest in those married but living apart from their spouses ($\chi^2 = 21.575$, $P < 0.01$). The rank order of the remaining groups is widowed, divorced, single and married. There is no significant difference between these last four groups. The GHQ while confirming the high rates of disorder among the separated ($\chi^2 = 19.623$, $P < 0.001$, produces a different rank order of separated, single, widowed, divorced and married. There is no significant difference in the last three groups. Thus the GPs, while correctly attributing high rates of disorder to people separated from their spouses tend to underdiagnose illness in single people. This is reflected in the high identification index found in the separated groups and the low identification index in single people and those married but living together.

These results are in line with the Manchester study in finding high rates among the separated group for GP and GHQ based indices.

Age left school

The conspicuous psychiatric morbidity falls from 28.7% in those who left school before 15 years of age to 14.3% in those who left school after the age of 16 years. This difference is greater than expected by chance ($\chi^2 = 16.106$, $P < 0.01$). The GHQ partly confirms this trend. The Manchester study used the variable of 'age left full time education' and found highest rates for CPM and probable prevalence in those with minimum education.

Socioeconomic class

This variable was not directly measured by Marks *et al* (1979). Rather, they used 'age left full time education' as an approximate indicator of social class. For the present study the Registrar General's classification was used, the social class of single women being based on their father's occupation. Subjects in social class V were too few to be included in the analysis. Conspicuous morbidity was highest in social classes I and IV (25% respectively) falling to 15.5% (Social class II) and 17.1% (Social class III). These differences were not significant ($\chi^2 = 3.43$, $P < 0.4$). The GHQ does not confirm this trend and again no significant differences were found ($\chi^2 = 6.41$, $P < 0.1$). No large differences were seen for identification index across social classes.

Dependents

This variable was not measured in the Manchester study. The presence of dependents did not affect the reporting of cases by the GPs. In each of the three classifications of dependents, there was no significant difference in conspicuous morbidity between those patients who had, and those who had no dependents. The GHQ reflected the GPs' judgements as there was no greater degree of GHQ caseness in those with dependents and those without.

The percentage of patients classified by both GHQ and GP as cases was highest in those who had elderly adults as dependents. In this group the proportion classified by both methods was identical to the CPM thus all reported cases were correctly identified. The identification was highest in those who had elderly adults as dependents.

National origin

This variable was not reported in the Manchester study. Conspicuous morbidity is highest among people born in the Republic of Ireland and lowest in those born in India. While probable prevalence is highest in the Irish, thus reflecting the CPM , it is also high among Africans who have a relatively low CPM. For neither CPM nor probable prevalence do the differences across national groups reach statistical significance.

The identification index is highest in those born in Eire and in those of miscellaneous national groups. The low values obtained in those of African and Indian origin may reflect the small number of these people in the sample ($n = 17$ and 13 respectively).

Discussion

Performance of the GHQ

One aim of the present paper is to report on probable prevalence of emotional disorders as measured by the GHQ and to compare this across two General Practice settings. This has been addressed by focusing on the number of probable cases detected and their sociodemographic composition. The study of Marks *et al* (1979) has been used for comparison as it was considered that the urban/semi-urban settings of Greater Manchester was comparable to that of Lewisham, and both studies have used a composite picture from a variety of general practices.

The GHQ was designed as a screening instrument and, as such, should properly be used as part of a two-stage procedure to select people for further interviewing (Goldberg, 1972). However, for certain purposes, such as for obtaining an estimate of psychiatric morbidity, it may be justifiable to use the GHQ alone. This one stage design should only be used in populations where the validity of the questionnaire is known and when the GHQ is used on new populations it should be revalidated (Goldberg, 1978). In general practice samples, the GHQ could be used alone as validity indices have been established and are generally acceptable (Goldberg, 1978). Clearly, whether a one-stage or two-stage design is used in such populations will depend on the purposes of the study.

Table VI shows the figures for probable prevalence obtained by use of the GHQ in several general practice studies and compares them to the conspicuous psychiatric morbidity as rated by the GP. The GHQ produces a wide variation in prevalence estimates but the estimates are obtained in a variety of settings and even when obtained in comparable settings (Goldberg *et al*, 1976; Marks *et al*, 1979; Skuse & Williams, 1984) the number of GPs from which the estimates were derived varied. It is of interest that Marks *et al* (1979), using several Manchester GPs obtained an almost identical figure to Schein (1977) in a sample of Philadelphia family practitioners. The lower figure for probable prevalence produced by Hoeper *et al* (1979) is probably due to the use of a different criterion of caseness than the other studies. Hoeper *et al* used the research diagnostic criteria (Spitzer *et al*, 1978) and Schedule for Affective Disorders and Schizophrenia (Endicott & Spitzer, 1978) while the other studies based their criterion on the Clinical Interview Schedule (Goldberg *et al*, 1970).

In the present study, by taking consecutive attenders at eight General Practices, an estimate of the prevalence of minor psychiatric morbidity was made and this proved to be comparable to that obtained in the Manchester study. The variations seen in GHQ cases across sociodemographic groups were remarkably consistent with the results obtained by Marks *et al* (1979). Marks *et al* compared their results to those of Shepherd *et al* (1966) and, with the exception of social class, showed them to be similar. Unfortunately social class was not measured directly in the Manchester study but instead, time spent in full-time education was used as an indirect measure. The present study used both variables and found that, while those people with a minimum education showed a high probable prevalence and conspicuous psychiatric morbidity there was no effect of social class. In the present sample age left school and socieconomic class were fairly strongly correlated ($\gamma = -0.509$) suggesting that education level provides a more sensitive index of morbidity than social class. The findings for social class obtained in this sample agree with those of Shepherd *et al* (1966).

The similarity of the results obtained for probable prevalence and sociodemographic distribution of cases in the Manchester and Lewisham samples serves to emphasise the reproducibility of results using the GHQ. It is not felt that use of different versions of the GHQ in the two studies had an effect

TABLE VI
Summary of data from studies using GHQ and GP ratings

Study	*Country*	*Number of physicians used*	*Version of GHQ used*	*Sample size*	*Probable prevalence: %*	*Conspicuous morbidity: %*
Marks *et al* (1979)	UK	91	60 item	4098	39.6	31
Goldberg *et al* (1976)	UK	1 practice	60 item	365	29.7	36.7

Chancellor *et al* (1977)	Australia	18	30 item	1301	51.7	14.3

on the results obtained as both have very similar validity profiles when used in general practice samples (Goldberg, 1978).

Performance of the General Practitioners

The most striking differences between the detection profiles of the Lewisham and Manchester GPs is the tendency of the Lewisham doctors to report less cases than their Manchester counterparts. The lower identification index of the Lewisham GPs is a secondary result of this lower bias as the accuracy in both groups of doctors is almost identical. The correlation between the detection indices are similar for both samples suggesting that the relationship between the indices remains stable in different groups of GPs with varying profiles. In both groups of doctors, accuracy is not predicted by either the GPs perception of the level of disorder or the estimate made by the GHQ. However, the ability to make accurate assessments is partly predicted by the ability to identify true positives and this later ability is strongly related to the tendency to make (or avoid making) psychiatric judgements. The differences in overall bias of the two groups suggests that the Lewisham doctors have a different conception of what constitutes a psychiatric case, adopting possibly more stringent criteria before reporting a patient as emotionally disturbed. This may reflect their different attitudes towards psychiatry and differences in their interview skills.

A surprising result is the finding concerning recruitment of symptomatic patients to female GPs. A study carried out in West Philadelphia found that high probable prevalence was associated with high bias (Schein, 1977). In addition the studies of Marks *et al* (1979) and Goldberg *et al* (1980) found doctors with a high bias to be 'interested in psychiatry', sensitive to verbal cues of psychological distress and to ask many questions of a psychiatric nature. It was thus expected that the patients with emotional distress would avoid GPs with low bias, however, the opposite was found. This contrary finding is explained by the low bias of the female GPs. It appears that symptomatic patients are attracted to women doctors in spite of their low bias. Perhaps these patients take their complaints to female GPs in the expectation that they may be more amenable despite them not recognising their psychological disorder. A further possibility is that these patients do not wish to be labelled as psychologically disordered preferring to receive treatment for their physical complaints. It is not possible to examine these possibilities with the present data.

As with the Manchester GPs, the Lewisham doctors, on the whole, confirmed the variations in probable prevalence as measured by the GHQ. In the examination of GP performance as case detector, the identification index provides the most important measures of detection as it is a measure of the ability to identify symptomatic patients as ill. Furthermore, computed in the manner used in this paper, it is not affected by prevalence.

It is likely that certain signals must alert GPs to the possibility of psychiatric illness. The signal indicators measured in the present study were the sociodemographic variables. High identification indices were obtained for women, middle-aged patients, housewives, the separated and widowed, patients with minimum education, the Irish and patients with elderly people as dependents. This profile can be seen to produce a positive stereotype almost identical with the perceived by the Manchester GPs. The construction of this stereotype is on the whole, justified by the high prevalence in these groups. Two notable exceptions are those of the widowed and of housewives. While the increased vigilance for widow(er)s may be understandable in terms of the attention paid to this group in the literature, for housewives the increased vigilance may have a more dubious basis perhaps relating to drug advertising and other media portraying this group as neurotic stereotypes (Stimson, 1975).

Other groups appear to constitute negative stereotypes for Lewisham GPs; these are men, young age-groups, single and married patients, those in full-time employment and patients of African and Indian origin. Again, these generally match the low identification groups found in the Manchester study.

The present study then, creates a similar picture for Lewisham and Manchester GPs' stereotypes. The positive stereotype is of the middle-aged housewife, with minimal education, separated from her husband, who may be looking after elderly relatives. This is in distinction to the negative stereotype of the young educated bachelor or recently married man in full-time employment.

Conclusion

The probable prevalence of emotional disorder and its sociodemographic distribution was found to be similar in Manchester and Lewisham general practices. The estimates of morbidity by the two groups of GPs however, are widely different with the Lewisham GPs providing a more conservative estimate. This reinforces the well-recognised finding that practitioners estimates of morbidity are an unreliable measure in epidemiological studies. However, the GHQ can provide more stable results. This is not to argue for abandoning a two-stage approach as suggested by Goldberg (1972), rather, it supports the use of the GHQ as a screening device for epidemiological studies.

The finding of a recruitment of symptomatic patients to female GPs requires further investigation. This finding has implications for the management of emotional disorders in general practice as it may mean that some patients with these disorders avoid situations where their disorder may be acknowledged.

The GPs' performances as case finders, as measured by identification index supports the contention that, when broad sociodemographic categories are used as measures of signal strength, the GPs use generally similar cues in their conception of case stereotypes. This suggests that stereotypes used by GPs may be generally rigid and may be generalisable across practitioner groups. The use of patient cues as indicators of GP caseness deserves further investigation as the cues utilised in the consultation will also be part of a GP's construction of a case and will be directly utilisable in increasing case detection by GPs. This may be usefully addressed by analysing the differences between GHQ and GP cases using patient variables. This requires a more detailed study than was undertaken here possibly involving analyses of doctor-patient interaction and follow-up of the patient using a two-stage design.

Acknowledgements

The study was supported by a grant from the Sainsbury Family Charitable Foundation. The author would like to thank Professor J. P. Watson, Dr N. Bouras, Dr T. Craig for their advice and Dr J. Mounty, Ms A. Burton, Ms L. James and Ms S. Axisa for their administrative help. He is particularly indebted to the Lewisham GPs for their invaluable assistance.

Ageing and Recovery from Alcoholism

G. NORDSTRÖM and M. BERGLUND

Fifty-five dependent (DSM-III) male alcoholics, chosen for good social adjustment, were personally followed up about 20 years after their first admission to hospital. The conditions of all the alcoholics were evaluated with a multidimensional diagnostic schedule when first admitted. At the follow-up, 11 were abstainers, 11 reported a change to social drinking via abstinence, and 10 reported a change to social drinking by gradual stages. Improvement after the age of 45 was mainly due to gradual change to social drinking. This type of improvement was in half of the cases attributed to a decreased tolerance for alcohol. In the present sample, there were no indications of any relationship between premature ageing and gradual change to social drinking. It is hypothesised that physiological processes of normal ageing with concomitant changes in reactions to alcohol may be of importance for remission from alcoholism in middle-aged and older alcoholics. The relationships of personality, social factors and the degree of alcohol-dependence to patterns of successful long-term adjustment are discussed.

Though several long-term follow-up studies of alcoholics have shown that a substantial proportion of the survivors eventually improve (Ciompi & Eisert, 1971; Öjesjö, 1981; Vaillant, 1983), knowledge about how processes of improvement evolve in relation to age is still limited.

Data from some general population and panel studies have indicated that many young problem drinkers, though they may have suffered quite severe social consequences of their abuse, tend to improve in their late 20s or early 30s (Fillmore, 1975; Saunders & Kershaw, 1979; Fillmore & Midanik, 1984). This type of improvement has been attributed to increasing maturity (Saunders & Kershaw, 1979; Fillmore & Midanik, 1984).

Other studies have indicated that alcoholism rates decrease with increasing age. Åmark (1951) found that the number of alcoholics admitted to treatment facilities decreased after the age of 50. Drew (1968) put forward the suggestion that alcoholism may be a 'self-limiting disease', with a tendency to resolution after the age of 40. In a personal follow-up of aged alcoholics in Switzerland, Ciompi and Eisert (1971) found that more than one-third of the subjects over 65 years of age were abstainers or moderate drinkers, improvement sometimes occurring after decades of heavy drinking. In a general population survey, Cahalan & Room (1974) found that the frequencies of different alcoholism symptoms were lower in subjects in their 50s and 60s. From other epidemiological studies, however, the frequency of alcoholism has been reported to change very little with ageing (e.g. Öjesjö, 1980; Mulford, 1982).

Ciompi and Eisert, as well as Drew, hypothesised that different biological, psychological and social aspects of ageing might be responsible for the amelioration of drinking habits with age. In the present paper, which concerns a follow-up, after about 20 years, of hospital-treated male alcoholics chosen for good social adjustment, we address the issue of ageing and recovery from alcoholism. We investigate whether there are any specific patterns of alcohol-adjustment or processes and mechanisms of improvement in alcoholics who improve when older compared with those who improve when younger. The possible relationships of background characteristics to such patterns and processes is studied.

Method

The sample

The present sample of alcoholics constitutes a subsample of a series of 1312 alcoholics who were first admitted to the Department of Psychiatry, University Hospital, Lund, Sweden, between 1949 and 1969. During these years the senior psychiatrists at the department rated their in-patients at discharge using a multidimensional diagnostic schedule developed by Essen-Möller (1961, 1971; Essen-Möller & Wohlfarth, 1947). The schedule consisted of one symptomatic or syndromatic part and one aetiological part. Among the aetiological items was 'chronic alcohol intoxication'. Those who scored positive on this item were included in the study, if they were first admitted as in-patients during

1949–1969 and lived in the county. The series has been reported on in previous publications (Berglund, 1984*a*,*b*, 1985). In order to obtain a group where a large proportion of the subjects had solved their alcohol problems, health insurance records were used. It has been shown that health insurance data relate strongly to the overall adjustment of alcoholics (Berglund, 1980). There were 324 patients fulfilling the following criteria: (a) male sex; (b) born 1916 or later; (c) first admitted 1949–1967; and (d) living in the county of Scania on 1 January 1981.

(A further 141 patients who fulfilled criteria (a) to (c) had died before 1981 while living in Scania (71 cases violent death, 70 cases other causes of death).)

Female patients were excluded to obtain a more homogenous sample. Patients born before 1916 were retired because of old age when the sample was followed up by health insurance data on 1 January 1981 and thus were not eligible for the present study, since the number of sickness cash benefit days was used as an inclusion criterion (see below). Patients admitted after 1967 were excluded in order to ensure an observation time of at least 15 years at the personal follow-up. The geographical delimitation was set for practical reasons. Out of the 324 patients, 70 (22%) fulfilled our criteria for good social adjustment, i.e. having at most 30 sickness cash benefit days during 1979 and 1980 together and a sickness cash benefit of at least 50 SEK/day. The figure of 30 sickness cash benefit days was the estimated unpublished median value for the male population of Scania for the years 1979 and 1980 together. The official mean value was 36.5 days. A sickness cash benefit of less than 50 SEK/day indicates part-time employment. These 70 patients constitute the sample of the present study.

Initial ratings and record data

At discharge after their first admission, all the patients were rated with a multidimensional diagnostic schedule as described above. For the present analysis, the main emphasis is put on the composite item 'personality disturbance with lack of internal control of behaviour', consisting of the items 'easily led, dependent, immature', 'psychopathic behaviour' and 'uncommitted, cold, uninterested'. These items were the ones that were seen as reflecting, in psychodynamic terms, an ego and/or superego weakness. This type of personality disturbance was more frequent in the abstainers than in the social drinkers ($P<0.05$). Otherwise, there were no significant differences between the abstainers and the social drinkers on the initial ratings.

The subjects who were married at the time of their first admission, who were not known to temperance boards, and who had a stable work record (according to the hospital records) and no criminal record, were categorised as socially stable, the others as socially unstable. Social stability at first admission was more frequent in the social drinkers than in the abstainers ($P<0.05$).

Personal follow-up

The subjects were contacted by mail and asked, according to rules set by the research ethical committee of the Faculty of Medicine, University of Lund, if they were willing to participate in a follow-up interview. The personal follow-up was carried out in 1982 and 1983. The interviewer (GN) was blind to all data about the subjects except age and year of first admission. The subjects were not informed in any way that the interviewer knew anything about the nature of the problems for which they were originally admitted. The interview was partly structured and partly open-ended. Sixty patients (86%) agreed to participate. Independent corroboration of the subjects' reports was obtained in 83% of the cases. The lost subjects differed from the ones who were interviewed, with a higher frequency of initial ratings indicating psychopathic behaviour ($P<0.001$), while available data indicated that outcome was about the same (Nordström & Berglund, 1986*a*). The length of the follow-up period was 21 ± 4 years. The mean age when first admitted was 32 ± 7 years and the mean age at follow-up 53 ± 7 years. The follow-up methodology and the interview technique, as well as details about different kinds of corroboration of the subjects' reports, are reported in detail elsewhere (Nordström & Berglund, 1987*a*).

The presence and severity of psychopathological symptoms at follow-up were assessed with the Comprehensive Psychopathological Rating Scale (CPRS) (Åsberg *et al*, 1978). The Drug Taking Evaluation Scale (DTES) (Holsten & Waal, 1980) was used to assess different aspects of psychosocial functioning at the time of the follow-up. Three of the four subscales were used (social functioning, social belonging, psychic status). On each subscale a global rating is made on a 9-step scale. Scale steps 1–3 indicate normal area, 4–6 symptom area and 7–9 illness area. The extent of the interview information obtained was in some cases too limited to permit reliable rating on the CPRS or the DTES. All patients were also asked about the main cause of improvement. In the present paper, only answers categorised as implying a decreased tolerance for alcohol are used in the analysis. The issue of causes of improvement has been dealt with in detail elsewhere (Nordström & Berglund, 1986*b*).

Classification of alcoholism

For the classification of alcoholism, both interview and record data were used. The classification was performed blindly with regard to initial ratings. Alcohol-dependence was assessed according to DSM-III criteria (American Psychiatric Association, 1980). For the retrospective year-by-year categorisation of drinking patterns, the Problem Drinking Scale (PDS), developed by Vaillant (1983), was used. This scale consists of 16 equally weighted items covering dependence symptoms as well as social and medical consequences of abuse. Subjects who had reached a cumulated score of 4 or more on the PDS were categorised as abusers for every year in which at least one score on the scale was noted, and as abstainers (if drinking no alcohol) or social drinkers if there was no score during the year. The mean number of drinks (one drink equal to 0.5 fl. oz) per month in the social drinkers was 25, range 5–53. Beer was the main alcoholic beverage consumed. Abusers with a more severe drinking pattern (> 3 abuse days per month, or > 2 weeks of continuous abuse per year) were categorised as

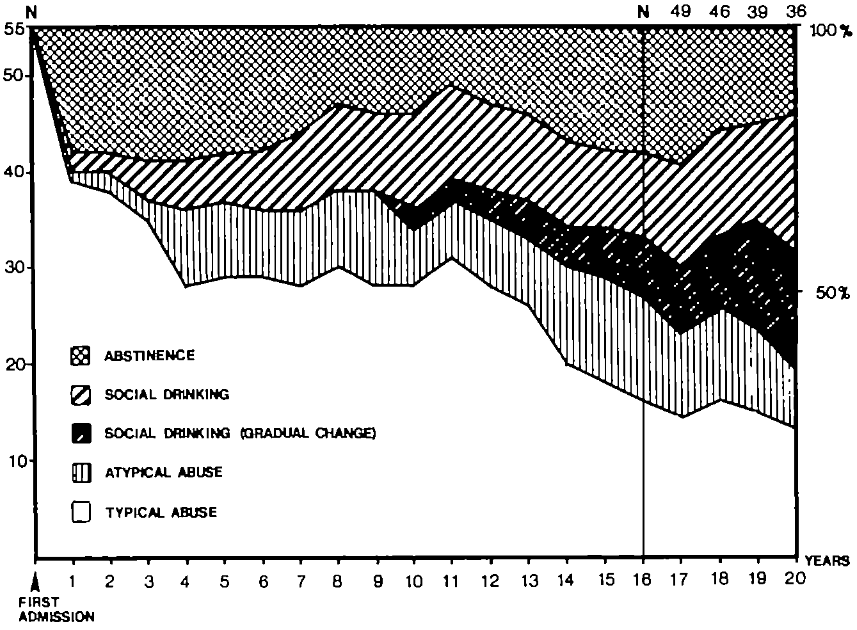

FIG. 1 Composite drinking patterns during the 16–20 years following first admission for the 55 subjects who had a lifetime diagnosis of Alcohol Dependence (DSM-III). All subjects were followed for at least 16 years after first admission. For years 17–20, percentages have been calculated for the subjects who were followed.

'typical abusers', and those with a less severe drinking pattern as 'atypical abusers' (Nordström & Berglund, 1987*b*).

In the present sample there were 55 subjects with a lifetime diagnosis of alcohol-dependence. Out of these, 13 were typical abusers at follow-up, 10 were atypical abusers, 21 social drinkers and 11 abstainers. The individual courses in atypical abuse (Nordström & Berglund, 1987*b*) and in social drinking and abstinence (Nordström & Berglund, 1987*a*) are reported elsewhere. Among the social drinkers, 11 reported a change by way of abstinence periods (mean duration 3 years), whereas 10 reported a change by gradual stages from problem drinking to social drinking. The present analysis is confined to the typical abusers, the social drinkers and the abstainers. The subjects who had never been alcohol-dependent were excluded.

Abstinence or social drinking were regarded as 'stable' when there was neither any relapse into typical abuse nor any longstanding relapse into atypical abuse. In three cases sobriety was regarded as stable although there were one or two isolated episodes of abuse of at most a week's duration, leading to a categorisation of the drinking pattern for the year concerned as atypical abuse. For another subject, a period of atypical abuse of a few months' duration, after a year of social drinking, was disregarded. Further, a month's relapse into typical abuse after 7 years of sobriety in one of the abstainers was disregarded concerning the question of stability of improvement.

Statistics

Differences between proportions were tested with the χ^2 test, or, if numbers were small, with the Fisher test (Siegel, 1956). Differences in distributions were tested with the Mann–Whitney *U* test (Siegel, 1956).

Results

Drinking patterns over intervening years

Figure 1 shows the composite course of drinking patterns during the 16–20 years following the first admission for the 55 subjects who had a lifetime diagnosis of Alcohol Dependence (DSM-III). The rate of sobriety (abstinence or social drinking) in the first year after first admission was 27%, changing very little during the first decade. After that, there was a gradual increase of the proportion of subjects attaining sobriety. The rate of improvement during the second decade was about 2–3% per year.

TABLE I

Initial ratings and record data related to drinking pattern at follow-up

	Drinking pattern at follow-up			
	Social drinking via gradual change	*Social drinking via abstinence*	*Abstinence*	*Typical abuse*
Number	10	11	11	13
Age when first admitted (median)	35	33	36	31
Heredity for alcoholism or personality disorder	4	6	6	7
Delirium tremens	0	3	3	2
Personality disturbance with lack of internal control of behaviour (A)	3	3^{1}	$8^{1,2}$	4^{2}
Social instability (B)	6	3^{1}	$9^{1,2}$	5^{2}
A+B	2	0^{3}	6^{3}	3
A or B	5	6	5	6
Neither A nor B	3	5^{1}	0^{1}	4
PDS score when first admitted (calculated retrospectively)	6.8±2.9	7.5±2.1	7.5±2.5	7.2±2.3

1. Comparison between abstainers and social drinkers via abstinence: Fisher test, *$P<0.05$.
2. Comparison between abstainers and typical abusers: Fisher test, *$P<0.05$.
3. Comparison between abstainers and social drinkers via abstinence: Fisher test, **$P<0.01$.

Abstinence was the most frequent type of favourable adjustment initially. However, 40% of those who were abstainers during some or all of the first 6 years after first admission were later to be found among the social drinkers. Gradual change to social drinking occurred later during the period and accounted for about 60% of the increase of sobriety rate seen during the second decade.

Initial characteristics related to drinking patterns at follow-up

Table 1 gives data about initial characteristics (initial ratings as well as record data) for the social drinkers with a gradual change, the social drinkers with a change by way of abstinence periods and the abstainers, compared with the typical abusers. Both personality disturbance with lack of internal control of behaviour, and social instability, were more frequent ($P<0.05$ for both) in the abstainers as compared with the social drinkers; also in comparison with the typical abusers. The social drinkers with a change by way of abstinence periods had the prognostically most favourable background characteristics in terms of personality disturbance and social stability.

Development and outcome characteristics related to drinking patterns at follow-up

Table II shows development and outcome data for the four outcome groups. There were no significant differences between the groups concerning age at follow-up.

The year when stable sobriety was attained differed significantly between the social drinkers with a change via abstinence (median 2 years after first admission) and those with a gradual change from abuse to social drinking (median 16 years) ($P<0.01$), and also between the social drinkers with a change via abstinence and the abstainers (median 10 years) ($P<0.05$). The social drinkers with a gradual change were older when stable sobriety was attained (median 51 years) than those with a change by way of abstinence periods (median 37 years) ($P<0.01$).

None of the social drinkers with a gradual change had ever had a delirium tremens, compared with five of the social drinkers with a change by way of abstinence periods ($P<0.05$). Five out of ten subjects with a gradual change from abuse to social drinking reported symptoms indicating a decreased tolerance for alcohol as mainly responsible for their improvement, whereas none of the subjects whose improvement had been related to initial or lasting abstinence did so ($P<0.01$).

As the follow-up, married status was more frequent in the social drinkers than in the abstainers or in the typical abusers, while the divorce rate was highest for the typical abusers. There were no differences between the three groups of subjects with favourable drinking patterns at follow-up concerning psychiatric symptoms, social functioning or social belonging. The abstainers and the social drinkers, taken together, scored lower than the typical abusers on the CPRS ($P<0.05$), and on the social functioning and psychic status subscales of the DTES ($P<0.01$) and the social belonging subscale of the DTES ($P<0.001$).

Discussion

Whether or not alcoholism is a 'self-limiting disease' (Drew, 1968) cannot be answered by this study. Further, the use of a clinical sample of male alcoholics limits the generalisability of our findings.

TABLE II

Development and outcome characteristics related to drinking pattern at the follow-up

	Drinking pattern at follow-up			
	Social drinking via gradual change	*Social drinking via abstinence*	*Abstinence*	*Typical abuse*
Number	10	11	11	13
Age at follow-up (median)	58	55	56	52

4. Comparison between social drinkers via abstinence and social drinkers via gradual change: Mann–Whitney U test, two tailed, **$P<0.01$.

The course of alcoholism in females has been reported to differ from that in males, with a more rapid progression (Stabenau, 1984; Hesselbrock *et al*, 1985). We do not know to what extent data on ageing and recovery obtained from male subjects are relevant also for females. The characteristics of our sample as regards age when first admitted prevents us from drawing conclusions concerning changes of drinking behaviour in younger age-groups. Differences between younger and older men as regards norms and expectancies concerning drinking behaviour have been hypothesised, indicating that in this connection the age variable may be strongly related to socio-cultural factors (Fillmore & Midanik, 1984).

Our sampling procedure also precludes us from studying the influence of physical illness on drinking behaviour, since the subjects who were investigated were selected on the basis of a low number of sickness cash benefit days. In an age-matched sample of alcoholics with a disability pension, which has been described in previous papers (Nordström & Berglund, 1986*a*, 1987*b*), four out of the five subjects who attained sobriety reported that physical or mental illness had been important in the improvement of their drinking habits.

The main finding of the present study was that the processes of improvement differed between older and younger alcoholics. Improvement in older subjects was related to a pattern of gradual change from abuse to social drinking. This type of improvement, which has been reported previously (Kendell, 1965; Bailey & Stewart, 1967; Knupfer, 1972), was responsible for most of the change to sobriety seen during the second decade after first admission and after the age of 45. The predominance of social drinking over abstinence in successful adjustment in older subjects is in agreement with the findings reported by Ciompi & Eisert (1971).

Animal studies have shown three main types of mechanism that might explain the changes in alcohol effects with ageing: a decreased rate of alcohol metabolism, possibly partly due to changes in hepatic functioning with increasing age; a decrease in body water, leading to higher blood alcohol levels; and neurochemical changes, with a subsequent increased sensitivity to ethanol of the aged central nervous system (Wood & Armbrecht, 1982. Bardo & Risner, 1985).

Though alcoholics with severe liver disease tend to decrease their alcohol consumption (Hermos, 1984), this does not seem to be a plausible explanation for improvement in the present sample. While subjects with pathological liver function blood tests in our sample were all typical abusers, there were no indications of liver damage in improved subjects. It has been reported that the decrease in body water with increasing age may contribute to a decreased alcohol consumption in man (Vogel-Sprott & Barrett, 1984). In the same study, however, evidence was found that the alcohol-induced impairment of behaviour when blood alcohol level was controlled increases with age, and it was suggested that this, too, may lead to a compensatory reduction of alcohol consumption.

In the present sample, the clinical state was the same in the social drinkers with a gradual change from abuse as in the social drinkers with an early improvement by way of abstinence periods or in the abstainers. There were no behavioural indications of premature ageing, with a subsequent decreased capacity for sustained heavy drinking. However, an increasing number of reports have shown that long-term sobriety produces a normalisation of alcoholics' brain-functioning, as measured by symptom check-lists (DeSoto *et al*, 1985), by neuropsychological tests (Berglund *et al*, 1977; Grant *et al*, 1984) by CT scan (Ron *et al*, 1982) or by regional CBF (Berglund *et al*, 1980. Ishikawa *et al*, 1986).

Thus, age-related alcohol-induced cognitive impairment cannot be discarded as a possible improvement-promoting factor in our sample. However, the preserved psychosocial functioning through years of abuse in our social drinkers with a change by gradual stages, could perhaps indicate that mechanisms related to normal ageing are more likely to have contributed to their improvement. Age-related changes in body water and in central nervous system sensitivity to alcohol, as referred to above, may be of importance in this respect. Another possible mechanism could be a decrease of the euphoric effects of alcohol due to changes in the levels of different neurotransmitters related to ageing (Winblad *et al*, 1978; Gottfries, 1980; Liljequist, 1979). The finding that five of the ten social drinkers with a gradual change, but no others, referred to symptoms indicating a decreased tolerance for alcohol as being important for their improvement could support the hypothesis that physiological processes of normal ageing may be involved in remission from alcoholism in middle-aged and older subjects.

It was observed that the background data for the social drinkers with a change via abstinence, who were those who improved earliest after their first admission and at the youngest age, were quite similar to the indicators of a 'good prognosis' described by, for instance, Davies *et al* (1956) and Vallance (1965), namely a good personality and social stability. The background characteristics for the social drinkers with a gradual change did not differ significantly from those of the other groups. Partly because of the low number of subjects, the difference between the two groups of social drinkers concerning the frequency of delirium tremens should be interpreted with caution. Possibly, the experience of a delirium may more strongly motivate for abstaining and be less compatible with a gradual cutting down of alcohol consumption.

To conclude, the findings from this long-term follow-up of socially well adjusted alcoholics indicate the existence of specific patterns and processes of improvement related to ageing. From the clinician's point of view, the results presented may perhaps be seen as implying that the prognosis for the middle-aged or older alcoholic who has managed to maintain good social adjustment is better than would be expected were only the duration of alcohol problems taken into consideration. Possibly, therefore, this group of alcoholics might be a suitable target group for intensified treatment efforts. On a general population level, suggestions of a similar kind have been put forward concerning the possible value of widespread information about the cerebral effects of alcohol in older people (Parker *et al*, 1982).

Alcohol, Other Drugs and Tobacco Use and Anxiolytic Effectiveness

A Comparison of Anxious Patients and Psychiatric Nurses

S. TILLEY

Recent studies raise questions regarding use or abuse of alcohol by phobics, and about compatibility of behaviour therapy and benzodiazepine use. In this study 40 patients, referred with mainly anxiety-related problems to a nurse behaviour therapist, and a comparison group of 40 psychiatric nurses completed a self-administered questionnaire assessing use of alcohol, sedative drugs and tobacco, and their perceived anxiolytic effectiveness. The paper confirms earlier findings that the patients, in general, drank less than the general public. They also drank less than the nurses, but used more sedative drugs and were heavier smokers. Alcohol was an unreliable anxiolytic. A few patients, including two agoraphobics, drank heavily and did not enter treatment made conditional on stopping drinking. Implications for case management are discussed.

The complex relationship between alcohol and sedative-drug dependence and anxiety-based problems poses thorny theoretical and clinical issues. A brief review of these will put the present study in context.

A number of studies have noted alcohol and sedative abuse among patients with anxiety-based problems (Marks *et al*, 1966; Sim & Houghton, 1966; Quitkin *et al*, 1972; Woodruff *et al*, 1972; Smail *et al*, 1984; Samarasinghe *et al*, 1984; Bibb & Chambless, 1986). Others have revealed a surprisingly high incidence of phobias among alcoholics (Mullaney & Trippet, 1979; Smail *et al*, 1984; Bowen *et al*, 1984). One question raised by these reports is whether people with anxiety-based problems become dependent on alcohol or sedatives through increasing and unsuccessful use of these drugs to quell anxiety; or whether heavy use precipitates or 'fuels' anxiety, especially phobic anxiety (Quitkin *et al*, 1972; Klein, 1980; Stockwell *et al*, 1984; Samarasinghe *et al*, 1984; Bowen *et al*, 1984; Bibb & Chambless, 1986).

Closely related is the question of clinical management. Some writers have advised treating alcohol or sedative abuse first, citing remission of phobias with abstention (Stockwell *et al*, 1984; Ashton, 1984). Others argue that treatment of dependence will fail if anxiety is not treated first (Quitkin *et al*, 1972). Miller (1986) reviews the pitfalls of concurrent treatment.

Behaviour therapists in particular have highlighted these clinical issues. Hafner & Marks (1976) and Chambless *et al* (1979) suggested that sedatives do not increase, and may reduce, the effectiveness of behaviour therapy for phobias. Sartory (1983) reviewed arguments about state-dependent learning and attribution of effects to drugs, concluding that sedatives should be stopped before behaviour therapy.

How often are problems of dependence likely to be encountered by clinicians treating anxiety-based problems, and what are sensible guidelines for managing such problems, in the absence of expertise in treating dependence? Samarasinghe *et al* (1984) surveyed the drinking and sedative use of 106 outpatients referred for behaviour therapy. They found that few drank to excess, and most found these substances unreliable anxiolytics. Patients generally complied with instructions to refrain from alcohol or drugs before sessions. With one exception, the few whose use was problematic stopped it when asked to do so as a condition of having treatment.

The present study provides more data on the use and reported anxiolytic effectiveness of alcohol and sedatives among patients referred to a nurse specialising in behaviour therapy. The methodology of Samarasinghe *et al* (1984) was in part replicated, as was their clinical practice of asking patients whose use of alcohol or drugs was seen as problematic to stop it before treatment, with referral for help with dependence if necessary. Tobacco use was also assessed. The patients' use of these substances was compared to that of a group of psychiatric nurses, chosen for convenience and because their judgement may be involved in assessment and management of patients' use; as well as to that of the patients reported in Samarasinghe *et al* (1984) and the general (Scottish) population.

Method

The questionnaire

This was based on the self-administered questionnaire used by Samarasinghe *et al* (1984). It had questions on usual frequency and quantity of alcohol and drug consumption; part use; and effects on anxiety, anticipatory anxiety and coping. In addition, patients were asked about tobacco use and anxiolytic effectiveness; and to report their previous week's drinking.

The respondents

Of 42 consecutive adult patients, 40 were asked to complete the questionnaire. All agreed. Twenty-six were male, 16 female; mean age was 37; 33 were out-patients, five in-patients, two day-patients; 18 were referred by psychiatrists, 15 by GPs, seven by others. Patients were retrospectively classified by the author into DSM-III categories where possible: agoraphobia with panic attack (ten); social phobia (eight); simple phobia (one); obsessive-compulsive disorder (five); marital problem (three); sexual dysfunction (two); intermittent explosive disorder (two); depressive neurosis (one); major depressive disorder (one); generalised anxiety (one); others (two); not classifiable (three). One patient denied having a problem.

Forty-two psychiatric nurses, matched for age (except two patients over 60 matched with nurses in their 50s) and sex, were asked to complete the same confidential questionnaire. Two declined.

Analysis

Results were analysed using χ^2 tests for independent samples or Fisher's exact probability test. The same tests were used for comparisons (see Discussion) with Samarasinghe *et al* (1984) and Dight (1976). In the latter comparison, percentages rather than numbers are compared to reduce distortion due to different sample sizes. Tests were one-tailed for sedative drug use, as patients were assumed to use more; and two-tailed for alcohol use, following Samarasinghe *et al* (1984) who found patients' drinking like that of the general population.

Numbers of responses reported are in some cases less than 40 due to incomplete questionnaires; similarly, percentages may be of the smaller numbers.

Results

Alcohol

Alcohol consumption is reported in units, where one unit equals 9 g alcohol.

On the whole, the patients drank less and less frequently than the nurses. In the previous week 27 patients (69%) reported drinking no alcohol; six (15%) drank 1–6 units; three (8%) 7–30 units; one (3%) 31–100 units; and two (5%) over 100 units. Ten nurses (26%) had drunk no alcohol; eight (21%) 1–6 units; 14 (36%) 7–30 units; seven (18%) 31–100 units; and none over 100 units. The difference between nurses and patients having a drink in the previous week was significant ($\chi^2 = 17.3$; d.f. = 1; $P < 0.001$).

Four patients (10%) reported usually drinking 6–7 days a week; seven (18%) 2–5 days; 15 (36%) once a week or less; and 14 (35%) were 'teetotal'. Among nurses, two (5%) usually drank 6–7 days a week; 16 (40%) 2–5 days; 19 (48%) once a week or less; three (8%) were 'teetotal'. Significantly fewer patients drank at least once a week ($\chi^2 = 8.5$; d.f. = 1; $P < 0.01$).

The amount drunk on a typical drinking day, for those nurses and patients who drank, was not significantly different. The heaviest drinkers were two agoraphobic patients, both of whom had received treatment for drinking problems. No female nurses, but 13% of female patients drank within a range said to involve a 'risk of harm' to health (36–64 units per week; Health Education Council, 1983). The two agoraphobics (9%) drank amounts indicating they 'may well be dependent' on alcohol. No male patients, but 13% of male nurses drank in the range involving a 'risk of harm' (51–95 units per week).

There were no significant differences in how often patients and nurses reported using alcohol for anxiety, nor in how effective they found it. Only three patients (8%) and no nurses always used alcohol when anxious; most in both groups never did so. The results were similar for anticipatory anxiety. Three patients (27%) and none of the nurses who took alcohol when anxious found it always helpful. Most found it sometimes helpful. Again, the results were similar for anticipatory anxiety.

Other drugs

Thirteen patients (33%) took minor tranquillisers; 15 (38%) antidepressants; two (5%) hypnotics. One nurse (3%) took minor tranquillisers; one (3%) antidepressants; one (3%) both. Altogether 24 patients (60%) and three nurses (8%) took one or a combination of these drugs ($\chi^2 = 24.65$; d.f. = 1; $P < 0.01$). Of the 16 patients (40%) not taking prescribed drugs, three (8%) used cannabis.

Four patients (11%) always took drugs other than alcohol when anxious; 14 (38%) sometimes; 19 (51%) never. Two nurses (5%) sometimes did so; the rest never. Six of those patients who took these drugs for anxiety (33%) always found them helpful; 11 (61%) sometimes; one (6%) never. One nurse found them helpful.

Tobacco

Twenty-two (55%) of the patients smoked, 14 (35%) of the nurses. Significantly more patients (nine; 23%) than nurses (none) smoked over 200 cigarettes a week ($\chi^2 = 5.18$; d.f. = 1; $P < 0.05$).

Seventeen patients and 11 nurses always or often smoked when anxious; six patients and eight nurses always or often found smoking when anxious made them feel better. There were no significant differences between nurses and patients in their use of tobacco for anxiety or its effectiveness.

Discussion

How valid is such a questionnaire? Self-report has strong face validity in assessment of perceived anxiolytic effect. While stringent checks on the accuracy of self-report of alcohol and drug use may not be feasible in the out-patient setting described here, the use of such measures has support from workers experienced in assessment of alcohol problems (Sobell & Sobell, 1975; Bernhardt *et al*, 1984), and is justified in the context of this study. Moreover, in further assessment and treatment of the patients, no grounds were discovered to doubt the reported level of drinking. The case of the nurses may be different. Nurses might be expected to under-report alcohol or drug use which could be seen as problematic, for fear of arousing professional concern. The validity of the nurses' self-report is also questionable given the finding that their estimates of usual drinking and last week's drinking differed significantly more often than did the patients', with last week's higher than usual ($\chi^2=8.23$; d.f. = 1; $P<0.01$). However, the fact that the nurses' drinking was still higher than that of the general population suggests that gross underestimation is less likely.

The reliability of the questionnaire is reinforced through comparison of the results for the patients in this study (referred to as the Dumfries patients) and the 106 patients reported on in Samarasinghe *et al* (1984) (referred to as the London patients). Both groups of patients were treated by nurse therapists with no expertise in managing dependence. Age and sex ratio were similar. Referred problems were broadly similar, with fewer phobics and obsessive-compulsive patients in Dumfries (60% compared to 78%; $\chi^2=4.97$; d.f. = 1; $P<0.05$).

The two groups were similar in the usual frequency of drinking and amount drunk on a typical drinking day; and in use and perceived effectiveness of alcohol for anxiety. Use of drugs and effectiveness were also similar.

One difference was notable. While there were no significant differences in drinking among different diagnostic groups in London, in Dumfries two patients, both agoraphobics, drank notably more than the rest – both 6–7 days a week, 114 and 119 units the previous week. Agoraphobics drank significantly more than other diagnostic groups in Dumfries (with 100 units as criterion, Fisher's exact $P<0.01$). This finding coincides with others (Bibb & Chambless, 1986) and indicates that agoraphobics may merit particular screening for alcohol dependence.

How does the drinking of the Dumfries patients and nurses compare with that of the general population? Table I summarises data on them and on people of like age and sex in a larger Scottish sample (from Dight, 1976). The categories are Dight's regular drinkers who had had a drink in the previous week; occasional drinkers who had not; and non-drinkers. The age groups compared are 20–40 as these contained most patients and nurses.

TABLE I

Proportions of drinkers and non-drinkers among Dumfries patients, nurses and Dight's sample (percentages)

	Dight	*Dumfries patients*	*Dumfries nurses*
Males 20–40			
Regular drinkers	84	30*	100*
Non-drinkers	2	10**	0****
Females 20–30			
Regular drinkers	58	57****	57****
Non-drinkers	6	14****	14****
Females 30–40			
Regular drinkers	56	14*	72***
Non-drinkers	3	72**	0****

*$P<0.001$; **$P<0.02$; ***$P<0.05$; ****NS
